This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

A PLEA FOR JUSTICE TO THE CONSUMPTIVE.*

A REPLY TO RECENT ATTEMPTS TO DISCRIMINATE AGAINST THE CONSUMPTIVE, NOT ONLY ON ACCOUNT OF HIS PHYSICAL INFIRMITY, BUT ALSO ON ACCOUNT OF HIS ALLEGED MENTAL AND MORAL DEFECTS.

BY S. A. KNOPF, M.D. (PARIS AND BELLEVUE, N. Y.), NEW YORK CITY.

VICE-PRESIDENT OF THE AMERICAN ACADEMY OF MEDICINE; HON. VICE-PRESIDENT OF THE BRITISH CONGRESS ON TUBERCULOSIS; VICE-PRESIDENT OF THE PENNSYLVANIA SOCIETY FOR THE PREVENTION OF TUBERCULOSIS; HON. DIRECTOR OF THE NEW HAVEN ANTITUBERCULOSIS ASSOCIATION; CORRESPONDING MEMBER OF THE INTERNATIONAL CENTRAL BUREAU FOR THE PREVENTION OF CONSUMPTION; MEMBER OF THE NEW YORK TUBERCULOSIS COMMITTEE OF THE CHARITY ORGANIZATION SOCIETY; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK; CONSULTING PHYSICIAN TO SANATORIUM GABRIELS, GABRIELS, N. Y.; ETC., ETC.

Mr. President, Fellow Members of the Society of Medical Jurisprudence, and Invited Guest:

IN order to plead my cause successfully before a distinguished audience of the jurists and physicians of this great metropolis, I must, to speak in legal parlance, state my case. To do this intelligently and conscientiously I will divide my discourse into three parts, and speak first, of official, second, of private, and third, of professional phthisiophopia.

Phthisiophobia means, in plain language, an exaggerated fear of the presence of a consumptive. Official phthisiophobia started in the United States about two years ago when the Surgeon-General of the Marine Hospital Service issued a declaration that pulmonary tuberculosis must be classed as a dangerous contagious disease, and that in future immigrants, or aliens visiting our shores, afflicted with pulmonary tuberculosis, must be debarred from all ports of the United States. In June of last year an order was issued confirming the above decision, and adding that tuberculous individuals should be debarred regardless of boards of special inquiry, which heretofore had used their discretion in the matter.

It goes without saying that none of us desire pauper immigration, and we do not want any such class to enter our country, whether they are tuberculous or not. The question here is simply: is it right, just, and scientific to declare pulmonary tuberculosis a dangerous, contagious disease, and exclude on that account worthy immigrants who offer a guarantee that they will not become a burden to the community, or to exclude aliens and visitors afflicted with pulmonary tuberculosis? Have those who have been instrumental in bringing about the Government decision to declare pulmonary tuberculosis a dangerous contagious disease, or who favor this decision, ever thought of the fearful meaning of a designation which virtually classes every American consumptive with patients who may be suffering from smallpox, leprosy, yellow fever, etc.? Have they ever thought how really few families there are who have not at least one, more or less near relative or friend who is a consumptive? Tuberculosis is the most frequent of all diseases, and it is most prevalent in the pulmonary form. It is a disease of the young and old, of the poor and rich, the East and the West, the North and the South.

I cannot do better here than to give you the concurrence of opinion of the medical profession of this city on this subject by reading to you the resolutions which I had the honor to present to the New York Academy of Medicine at the time, and which were seconded by Prof. Edward G. Janeway of this city and adopted by the Academy at its regular meeting on February 6, 1902:

Whereas, The Treasury Department of the United States, upon recommendation of the Surgeon-General of the Marine Hospital Service, has recently decided to classify pulmonary tuberculosis with dangerous contagious diseases, Be it

Resolved, That the New York Academy of Medicine deeply deplores this decision, which is not based on either clinical experience or on scientific experiments. Be it further

Resolved, That the Academy considers the exclusion of non-pauper tuberculous immigrants and consumptive aliens visiting our shores unwise, inhumane, and contrary to the dictates of justice. Be it further

Resolved, That, while the Academy is convinced of the communicability of tuberculosis and urges all possible precautions against the spread of the disease occasioned by sputum and tuberculous food, the Academy is opposed to all measures by which needless hardship is imposed upon the consumptive individual, his family and his physician.

The secretary of the Academy was instructed to forward a copy of the resolutions to the Treasury Department, the Surgeon-General of the Marine Hospital Service, and to the secretary of the New York State Medical Society.

Of the men who stood on my side at the time I presented these resolutions and helped me to carry them, I wish here to remember gratefully Prof. Edw. G. Janeway, Prof. Hermann M. Biggs, Prof. T. Mitchell Prudden, Prof. Geo. M. Peabody, Dr. A. H. Doty, the Health Officer of the Port of New York; Dr. Aug. J. Lartigau of the Pathological Department of Columbia University, Dr. Geo. B. Fowler, Ex-President of the New York County Medical Society; Dr. Geo. F. Shrady, Editor of the MEDICAL RECORD; Dr. Andrew H. Smith, the present president of the New York Academy of Medicine, and Dr. Frank P. Foster, editor of the *New York Medical Journal*.

Let me also give you a few opinions of men outside of our own city on this vital question. Dr. Geo. M. Gould, the editor of *American Medicine*, in a leading editorial on this subject, said: "We think professional and lay opinion will not justify the exclusion of tuberculous immigrants on the simple ground that the disease is 'contagious' or 'communicable.' It is only so in such a low degree that the severe measure of exclusion for this reason alone seems unjustifiable." Dr. Geo. H. Simmons, editor of the *Journal of the American Medical Association*, the representative organ of the American medical profession, says in regard to the resolutions: "The resolutions presented to the Academy of Medicine are to the point and express the opinion, I believe, of about 90 per cent. of the best men in the profession who have given thought to the subject." Dr.

*Read before the Society of Medical Jurisprudence, on December 14, 1903.

U. O. B. Wingate, the secretary of the Wisconsin State Board of Health, expressed himself regarding this matter as follows: "The action of the head of the Marine Hospital Service in this matter is simply inhuman."

To the best of my knowledge this almost universal protest on the part of the medical profession of this country regarding the decision of the Surgeon-General, acting under the authority of the Treasury Department, has to this date remained unheeded.

Before I speak of the results of federal official phthisiophobia on the general public, let me proceed to a chapter of State phthisiophobia. I do not wish to arraign here the attempts of certain California and Colorado statesmen who wish to exclude phthisical invalids from their borders, but I shall confine myself to our own State, New York. Our present Governor has, by the signing of the Goodsell-Bedell bill, at the close of the last Legislature, put himself on record as one favoring official phthisiophobia.

What is this Goodsell-Bedell law? Under the law of 1900, Chapter 327, cities of the first class were authorized to erect sanatoria for the treatment of consumptives outside the city limits, such acts and the selection of the site to be subject to the approval of the State and local Boards of Health. Private property was sufficiently protected by the general laws. The effect of the Goodsell-Bedell law is to make it hereafter practically prohibitive to establish such a sanatorium anywhere in the State. If any board of supervisors of a county or a town board should be opposed to the establishment of an institution for consumptives, the mere adoption of resolutions would suffice to make the creation of such an institution impossible.

The Governor was implored from all sides not to sign the bill. The New York Academy of Medicine protested, as it usually does when there is danger to the public health and welfare from injudicious legislation, and passed the following resolutions on the subject:

Whereas, There has been recently passed by the Legislature of the State of New York an act to amend the public health law in relation to the establishment of public sanatoria, hospitals, or camps for the treatment of tuberculosis, which act reads as follows: "A hospital, camp, or other establishment for the treatment of patients suffering from the disease known as pulmonary tuberculosis shall not be established in any town by any person, association, corporation, or municipality, unless the Board of Supervisors of the county and the town board of the town shall each adopt a resolution authorizing the establishment thereof, and describing the limits of the locality in which the same may be established," and

Whereas, The effect of this bill, if it becomes a law, will make it impossible for any city in the State, or any fraternal order, charitable society, or philanthropic individual, to establish a hospital, camp, or other establishment for the treatment of consumptives, outside of the city limits, except under conditions which are practically prohibitive, and

Whereas, By chapter 327 of the laws of 1900, cities of the first class are authorized to erect sanatoria outside of the city limits, such action and the selection of a site to be subject to the approval of the State Board of Health, and by the same law, hospitals and institutions, now, or hereafter established or maintained, are made subject to the approval of the local board of health, and

Whereas, Private property rights are sufficiently protected by general laws, and the process of injunction is open, in case it can be positively shown that unwarranted injury would be inflicted by the establishment of a hospital on a particular site, and the necessity of obtaining the consent of the State Board of Health being an ample guarantee that a site shall not be selected which shall threaten or unduly expose the health of any particular neighborhood, and

Whereas, It has been demonstrated in this country and in Europe that properly conducted sanatoria, hospitals, and camps for consumptives are not a danger to the neighborhood, and that such institutions are places where the consumptive poor receive a hygienic education and have the best possible chance to be cured and become again useful citizens and supporters of families, and

Whereas, There is at present a great deficiency of hospital accommodation in New York State for this class of patients, Be it therefore

Resolved, That the New York Academy of Medicine deeply deplores the passage of the above bill, and urgently requests his Excellency the Governor, to withold his signature to the act, which, in case it became a law, would involve the loss of thousands of lives and increase the spread of tuberculosis within the crowded districts of our cities and towns, and would have to be considered an act of the greatest injustice and inhumanity.

Similar resolutions were passed by the New York State Medical Society, the New York County Medical Society, the New York County Medical Association, and the medical societies of Buffalo and Syracuse. The Committee on the Prevention of Tuberculosis of the Charity Organization Society appealed to the Governor for the same purpose through its Secretary, Mr. Edward T. Devine, by a lengthy and explicit letter. The Grand Secretary of the Grand Lodge of Free and Accepted Masons of the State of New York, M. W. Edward M. L. Ehlers, wrote on behalf of the masonic fraternity, earnestly requesting the Governor to withhold his signature from the Goodsell-Bedell bill.

Of leading citizens who have since communicated with me and approved of a repeal of this inhumane law, I may be permitted to mention the Right Rev. Bishop Potter, Rev. Minot J. Savage, the Hon. Carl Schurz, Commissioner Homer Folks, Mr. Lee K. Frankel, Mr. Jacob C. Schiff, Mr. I. N. Phelps Stokes, Mr. Nathan Straus, the Hon. Theodore Sutro, Miss Lillian D. Wald, the editors of all our leading New York medical journals, Professor Francis P. Kinnicut of Columbia University, Professor Hermann M. Biggs, Chief Medical Officer of the City of New York, Dr. Henry L. Elsner of Syracuse University, Dr. Arthur W. Hurd, Superintendent of the Buffalo State Hospital, Dr. A. L. Benedict of Buffalo, Dr. Addison W. Baird of this city, and others.

In commenting upon the Governor's apology for signing this bill in spite of the many protests, the editor of *Charities*, the organ of the New York Charity Organization Society, says: "All that we can say is that undue consideration seems to us to have been given to the 'property interests' to which the Governor refers and none at all to the consumptives, of whom some twenty thousand will die of their disease in the State of New York this year."

There is a reason why I appear before this audience, composed of men of law and men of medicine. As a humble representative of the latter I come to you, leading representatives of the bar of New York to help us medical men to have this infamous law repealed. We must have sanatoria to save the lives of thousands of our fellow citizens, and there must not be on the statute books of this great State a law whereby a municipality or a philanthropist could be prevented from establishing a sanatorium, providing the ordinary rules and regulations for such an institution are complied with.

What has been the result of this Federal and State phthisiophobia on smaller authorities, such as municipal, town, and village boards? Municipalities, situated in particularly healthful regions, which formerly allowed their unsupervised boarding-houses to be crowded with consumptives—which was unsafe and unwise—have gone now to the other extreme, prohibiting the establishment or the existence of well-conducted sanatoria in their neighborhoods. Yet it is known to us all that there is not the slightest danger from well-conducted sanatoria; they are, on the contrary, veritable schools of hygiene, exerting a most beneficial influence by educating the people at large in preventive measures.

As soon as town or village boards learn that the establishment of a sanatorium is contemplated in the vicinity of their respective communities, they come together and simply oppose every movement favoring such a plan. Those of us who are occasionally asked to help in selecting a site for a sanatorium for consumptives will bear me out when I say that at the present time there is nothing more difficult in our beloved State than to find a suitable site for a sanatorium in a community which would welcome the establishment of such an institution. The small municipalities, the towns and villages are now strengthened in this insane prejudice by the Goodsell-Bedell law. Yet, as I have proved again and again by most reliable statistics, instead of a danger sanatoria for consumptives are a blessing to the neighborhood. In the two German villages, Goerbersdorf and Falkenstein, where five of the most flourishing sanatoria for consumptives have been in existence for the last fifty years, the mortality from tuberculosis among the inhabitants of the respective villages has decreased by one-third from that which it was before the establishment of the institutions. This remarkable result is simply due to the fact that the villagers voluntarily imitate the hygienic precautions which are obligatory to the inmates of the sanatoria.

Again, the well-known fact that in carefully conducted and well-equipped sanatoria, where the precautions concerning the sputum are most strictly adhered to, one is safer from contracting tuberculosis than perhaps anywhere else, should open the eyes of these narrow-minded and prejudiced village authorities.

There is an urgent and crying need for more sanatoria for the treatment of tuberculous patients, and the sooner the Goodsell-Bedell law is repealed the better it will be for the financial as well as the sanitary conditions of these very communities who are now opposing the establishment of such institutions. These sanatoria educate and cure at the same time; they cure the curable, and when patients are sent there at the right time, they have at least 75 per cent. of chances of being cured, and this often in less than a year's time. Not treated and not tured, they will cease to become breadwinners and linger often as burdens to the communities for one or two years.

In contrast to the stand taken by the Governor and the Legislature of the State of New York, in enacting the Goodsell-Bedell law, let me tell you of the different spirit which animated the late New Mexico Legislature. Chapter 17 of the law of New Mexico of 1903 provides that any company or corporation which shall, within one year from the passage of this act, commence and within two years after the passage of this act shall have expended at least $100,000 in the construction of a sanatorium in New Mexico for the care of invalids and persons with tuberculosis and other pulmonary diseases, shall thereafter be exempt from taxation on all property actually used in connection with such sanatorium for a period of six years after the expiration of two years after the passage of this act.

Private phthisiophopia has resulted partially from the Federal and State phthisiophobia just discussed, and partially from the excessive caution of those who are not sufficiently educated in the matter. Let me give you a few instances of the form it takes: Poor sewing women have been discharged, not because they were consumptive themselves, but because they were imprudent enough to mention in the presence of their employers that they were living with or were related to some consumptive. Employees in offices, having an innocent cough, are discharged for fear of contagion. Of the number of cases of phthisiophobia which came under the observation of Prof. A. Jacobi of this city, and which he was good enough to relate to me, one seemed particularly pathetic. A man with a large family to support, but strong, vigorous, and of excellent physique, was discharged from employment because of a non-tuberculous cough which, however, did not get well fast enough to suit his employer.

Had the following case not come under my observation, I would not have thought it possible that phthisiophobia could be productive of such cruelty. The husband of a woman of beautiful character, and devoted as only a woman can be, declared that since there was no longer a doubt that his wife was suffering from consumption he would have to leave her, for he would take no chances. The little sweet-faced sufferer proved to be a most conscientious patient and most eager to carry out all the precautions which would render her a safe companion to associate with.

I wonder if the Surgeon-General of the Marine Hospital Service and his advisers, our solons at Albany, and our distinguished Governor ever realize the sufferings of mind and body they have caused by fostering this new disease, phthisiophobia? Heart-rending as the results of this senseless fear, senseless ruling, and senseless legislation have been to the unfortunate persons afflicted with tuberculosis, still more serious are the results of this official phthisiophobia in its sequel of an exaggerated fear of the presence of consumption considered from another point of view. Individuals who suffer with the early symptoms of tuberculosis, or others who feel themselves in danger of becoming consumptive, will hesitate to seek medical advice for fear of being declared to suffer from a dangerous contagious disease and becoming subject to social ostracism. What a fearful loss of life a retarded diagnosis in pulmonary tuberculosis means, I need hardly dwell upon in an audience of this type. All our hopes in phthisio-therapeutics are centered on the early recognition of pulmonary consumption. Our American sanatoria report as many as 75 per cent. and more of recoveries of incipient cases. How very much lower the percentage of cure is when the patients have passed the incipient stage we all know only to well.

Now comes what I consider the saddest thing of all, namely, the professional phthisiophobia. Thank God, it is rare, very rare; but the recent appearance of an article on "Psychical Relations of Tuberculosis in Fact and Fiction" shows that there is also in our own ranks at times a manifestation of phthisiophobia. The article referred to is from the pen of a Dr. G. A. De Santos Saxe, and appeared in the *New York Medical Journal* of August 1 and 8, 1903. I have neither time nor inclination to refute all the conclusions this young author has come to from his reading and experience, but I will only quote two of his remarkable statements. Quoting another author, who had found a number of patients disregarding his orders concerning the care of their expectoration, and observing *one* who had expressed the wish that his young wife should not survive him, Dr. Saxe says the following: "To me this account shows the germination of a homicidal tendency, which is the resultant of the psychical defects that I have outlined in my analysis of the average consumptive's mental peculiarities. Here, psychasthenia, the loss of self-control, and the rise of brute selfishness have combined to distort the clearness of ethical perception." . . . "The funda-

mental factors in the psychical make-up of the typical consumptive are the loss of self-control, the rise of brute selfishness, the increase of susceptibility to suggestion, to emotion, and to nervous irritation, and the tendency to rapid nervous and psychical fatigue."

While I may, perhaps, claim that I have had a somewhat extensive experience with consumptives of all classes of society, in special hospitals, health resorts, and private and consultation practice, which might entitle me to refute the statements of Dr. Saxe, let me first give you a few extracts from letters which I have received from some of our leading authorities on this subject in answer to a letter of inquiry.

In this letter I gave the name and date of the journal containing Dr. Saxe's article, quoted the above-mentioned conclusions at which the author of that article had arrived, and asked the following questions: (1) In your vast experience with consumptives, have you ever noticed among them a greater tendency to immorality or crime than among individuals afflicted with other diseases, or among well persons? (2) In your opinion, is the average consumptive inclined to brute selfishness, to loss of self-control and consequent distortion of the clearness of ethical perception?

Dr. Lawrence F. Flick, Medical Director of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis, of Philadelphia, says: "I have not, in my experience, noticed among consumptives a greater tendency to immorality or crime than among individuals afflicted with other diseases."

Dr. Arnold C. Klebs, one of the founders of the Committee on the Prevention of Tuberculosis of Chicago, and a well-known specialist on consumption, writes: "In my estimation it is a great mistake to use such instances as cited by Dr. Saxe, for artificial construction of a consumptive type. There is no such thing as a specific psychopathology of tuberculosis."

Dr. Edward D. Fisher, Professor of Nervous Diseases at Bellevue University Medical College, said: "There is no special form of insanity due to tuberculosis. Tuberculosis is more common in the insane as a result of the lowered vital condition than as a cause of mental disease."

Dr. Edward O. Otis, Professor of Climatology at Tuft's Medical College at Boston, and well known by his writings on sanatoria and tuberculosis, says: "I can say emphatically that I have had not the slightest evidence, in my long experience with consumptive patients in all stages of the disease, that there was any greater tendency to immorality and criminality than among patients afflicted with other diseases or among well persons. In fact, I would put it this way: That there was no greater tendency to immorality and criminality among consumptives than among well persons. Secondly, I have never, in my remembrance, had cases of distorted moral vision."

Dr. James Tyson of Philadelphia, Professor of Clinical Medicine, of the University of Pennsylvania, writes: "I am thoroughly in sympathy with you in the feeling that there is a ridiculous phthisiophobia now prevalent which is far more selfish than any conduct I have observed in the average consumptive. I am totally out of sympathy with the methods which have been pursued to discriminate against the consumptive."

Dr. Hermann M. Biggs, Professor of Clinical Medicine of the Bellevue University Medical College and Chief Medical Officer of the Health Department of this city, says: "I have never noticed any special tendency to immorality or crime among individuals afflicted with tubercular diseases; nor do I believe that there is any greater evidence of selfishness, loss of self-control, or distortion of ethical perception in them than in other persons."

Dr. Edward G. Janeway, Professor of Clinical Medicine and Dean of the Bellevue University Medical College, has this to say: "I have not noticed any such tendency as you inquire about on the part of consumptives as regards immorality or crime as compared with well people or with those ill with other diseases, placed under similar circumstances. It is to be remembered that criminals and the insane are prone to be victims of tuberculosis, and hence someone who studied this class of people would be liable to form very unjust views about the consumptive class as a whole. Nor is it my experience that the average consumptive is inclined to brute selfishness, loss of self-control, and hence distortion of the clearness of ethical perception. I have found so much to the contrary that I am surprised at so broad a charge against the consumptive invalid."

Dr. Sherman C. Bonney, Professor of Medicine at the University of Denver and member of the Board of Managers of the Denver Home for Consumptives, writes as follows: "From a close personal experience with something like two thousand private patients afflicted with pulmonary tuberculosis I have noticed a far less tendency to immorality or crime than among individuals afflicted with other diseases, or among the well. In answer to your second question I will state that it is my conviction rather than being inclined to brute selfishness, loss of self-control and consequent distortion of the clearness of ethical perception, the consumptive exhibits precisely the opposite tendency. It is my experience that in an exceedingly large class pulmonary invalidism works in precisely the opposite direction, toward patience, sympathy, self-restraint, a new gentleness and a greater charity."

Dr. William Osler, Professor of Medicine of Johns Hopkins University and Physician in Chief of Johns Hopkins Hospital in Baltimore, writes as follows: "I quite sympathize with you in your movement, and in reply to your questions I would say: first, I have never noticed among consumptives any greater tendency to immorality or crime than in other individuals, I should rather say the contrary. My impression is that the unfortunate victims of tuberculosis are above the average in their mental and moral character; secondly, I should say emphatically that the average consumptive is neither inclined to brute selfishness nor any special distortion of the ethical perceptions. I am glad you called my attention to the article in the *New York Medical Journal*. So far as my experience goes, such statements as you say are made therein are an unwarranted slander."

Dr. Vincent Y. Bowditch of Boston, Founder and Physician in Chief of the Sharon Sanatorium for Consumptives, and visiting physician to the Massachusetts State Sanatorium, writes as follows: "I have read Dr. Saxe's article. The remark which you quote is entirely unjustifiable, judging from my own experience of more than twenty years' association with consumptive patients. Doubtless we come across *individual* cases of selfishness and of loss of self-control; but such symptoms are, to me, simply an exaggeration through disease of elements *which existed in the patient's character before the illness ever appeared*. Certainly I can give my testimony to innumerable cases of patient suffering, of unselfishness, and of heroic struggle against weakness and nervous irritation. In answer to your question number one: I have not noticed "a greater tend-

ency to immorality or crime than among individuals afflicted with other diseases, or among well persons." I decry every such statement made by our medical brethren which shall tend to increase the already insane fear of tuberculosis which exists in a large portion of our community. You know perfectly well my position in the matter. I can say this, however, that I have certainly seen, in consequence of this fear, the most brutal exhibitions of selfishness among the friends and relatives of patients suffering with pulmonary disease, and more than I have ever seen among those afflicted. Hoping that this may be of service to you in your endeavor to help the trying position of every consumptive, I am, etc."

I have received one more letter, and I read it last because I treasure it most. It comes from a man to whom all who know him personally, and all who know his works, look up not only as a great physician, scientist, and specialist on tuberculosis and the pioneer of the sanatorium treatment in this country, but also as a great humanitarian and a most noble character and example what a man, though consumptive himself, can do for his fellowmen. Dr. E. L. Trudeau, who twenty years ago, as a seemingly helpless invalid, made his home in the wilderness of the Adirondack Mountains, became through his untiring work, his unselfish devotion to science and the highest ideals of human helpfulness, the founder of one of the most beautiful and flourishing sanatoria for the consumptive poor in the world, the founder of a prosperous village crowded with consumptives of the wealthier classes, a teacher to the medical profession in practical phthisio-therapeutics and a teacher in practical philanthropy to the American public and the world at large. These are his words:

"I have never noticed any greater tendency to immorality or crime among consumptives than is to be found in the average of the human race, as far as it has come under my observation. On the contrary, I have seen all the finer traits of human nature developed to the fullest extent by the burdens which chronic and fatal illness, often slow in its progress, adds to the sum total of what men and women usually have to endure in life. I have seen certainly more patience, courage, self-denial, and unselfish devotion to others in consumptives than I have noticed in the majority of healthy human beings. Indeed, the sanatorium work never could have been carried on were it not for the self-sacrificing devotion to the suffering of others shown by my associates, the nurses, and even the employees at the sanatorium, most of them having come here originally because suffering from tuberculous disease. History is full of instances which prove that tuberculosis does not interfere with the development to the highest degree of the intellectual, the moral, or the ethical sides of man's nature."

It would hardly seem necessary after this array of opinions from men in the very height of the medical profession, to add my own opinion, though based upon an experience of many years of practice among consumptives in different climes and different countries, and among men and women in all stations of life. I may say that I have not only practised but also lived among them and with them, and from all my experience I can only confirm what has been said by the great authorities just mentioned. Never have I noticed consumptives to be more inclined to immorality or crime than individuals afflicted with other diseases, or even well people; only in a few instances have I noticed real selfishness, and never what one could call a distortion of the clearness of ethical perception, among them. On the contrary, as in the experience of Drs. Osler, Janeway, Trudeau and Bowditch, it has always seemed to me that many consumptives are above the average in their mental and moral characteristics. Instead of brute selfishness, I have frequently witnessed the most touching evidences of self-sacrifice and devotion. I have seen colleagues in institutional and private practice, trained nurses and sisters of charity, who, though they knew they had contracted tuberculosis in the pursuit of their professional duties, did not leave the battlefield, but continued to labor and help their consumptive fellow-sufferers. Two of my most beloved teachers, to whom I owe an everlasting debt of gratitude for the inspiration and help they have given me in my work, Professor Grancher of Paris and Geheimrath Dettweiler of Falkenstein, were both consumptive. They have taught and practised among consumptives for a quarter of a century, and are still leaders in the anti-tuberculosis crusade in Europe.

Among the sweetest experiences and recollections of my life I will always count the gratitude of the consumptive poor or rich, expressed either at the assurance of their recovery or for the care bestowed upon them when their case was beyond human help.

After this, my personal testimony, resulting from my experience with sane consumptives, let me again refer to the letters of Professors Janeway and Fisher in regard to the frequency of tuberculosis among the insane and criminals, and be permitted to add my opinion on this subject. While it is true that the lowered vitality in many insane invites the invasion by the tubercle bacilli, just as privation and misery of social origin predispose to consumption on the one hand and often invite the heretofore honest individual to become a criminal, to my mind the frequency of tuberculosis among the insane and criminals has other sources. The close confinement in insane asylums and in prisons, the lack of exercise and the depressing influence of institution life, but, above all, the close contact with the inmates who are already tuberculous, the want of sanitation and proper hygienic precautions in many of our insane asylums and prisons, and, lastly, the lack of facilities in treating the tuberculous, are the main factors of the frequency of tuberculosis in the insane asylums and prisons.

That insane tuberculous patients can be isolated and cured of both their physical and mental infirmities, has been beautifully demonstrated by the tent life inaugurated by Dr. McDonald and his associates at the Manhattan State Hospital for the Insane on Wards Island. That something can be done for the tuberculous prisoner to cure his tuberculosis and make of him a useful and healthy member of society, has been demonstrated by the Texas Agricultural Colony for tuberculous prisoners. Let me incidentally mention that $25,000 remained as net earnings during the first year of its existence.

There is a great and urgent work in this direction before our public sanitarians, the managers of insane asylums and prisons of our own and many other States. It is our right and our duty to confine the mentally deranged in an asylum for his own good and that of others, but in doing so we must protect him from contracting other diseases. For the good of society we must also confine the criminal, and it is our right to punish him by years of seclusion according to the gravity of his offence. But however great the crime he may have committed, we have no right to sentence him to contracting tuberculosis, which, as prison life is now in most of our States, must almost invariably result in death.

There are probably at this moment in the United States from six to seven million tuberculous patients. The Treasury Department classifies their disease as dangerous and contagious, like leprosy, smallpox,

and yellow fever. Thus, in spite of the opinion of the best authorities in the United States and also the Academy of Medicine of New York, the Government stamps several million of American citizens with a stigma wholly undeserved. Annually 150,000 of these consumptive patients, living in the United States, will die of this disease, and three times that number will be attacked in the same period unless more rational methods of prevention and cure are universally instituted than heretofore. For the State of New York, I believe, we are safe to say that at least 45,000 will become tuberculous annually, and 15,000 will die from the disease.

Yet, modern science declares consumption a preventable and very often curable disease. The prevention of consumption naturally lies not only in the precaution necessary to prevent the transmission of the disease from one human being to another, but also in the betterment of the social conditions of the majority of our laboring classes. They must be better housed and fed. So long as we allow the poor to be housed in dark, dreary tenements, where sun and light rarely enter, so long can we hope for no appreciable decrease in the frequency of tuberculosis. Never was the need of more model tenement-houses and the creation of more parks and playgrounds in our crowded tenement districts more strongly impressed upon my mind than when, a few weeks ago, I visited the famous "lung block." I wish I had the pen of a Jacob Riis to describe to you in vivid language what I saw during my visit to this plague spot. The peculiar odor, so characteristic of badly housed humanity, the dark bedrooms in which no ray of sunshine ever entered, the ill-smelling and badly-kept school-sinks, and the pallor of the faces of the emaciated tenants—adults and children—I shall never forget. When looking in the faces of the large number of children, whose playground was the little space between the back and front tenements, half of which was occupied by the ill-smelling water-closets, I thought I could discern among them many little candidates for consumption. No wonder then, when tuberculosis has once made its appearance in such environments, it becomes an epidemic disease and its eradication is only possible by erasing the buildings. As you know, this "lung block," which is the home of a thousand families, is that section of the lower east side which is bounded by Cherry, Market, Hamilton, and Catherine streets. The Board of Health, as well as the Tenement-house Commissioner, have done their very best to improve the insanitary condition, but realizing that remedial agents were of no avail, the destruction of the block and its replacement by a park was recommended to the Board of Apportionment. The matter is now under consideration, and I hope that wise council will prevail. In the meantime let us hope that some philanthropists will arise who, instead of libraries and churches, will build a number of model tenement-houses where honest laborers may find, for a reasonable price, heathful and sanitary homes. The time has come, however, when purely philanthropic enterprises in regard to model tenement houses no longer suffice. Municipalities as large and as rich as ours should consider the feasibility of undertaking to build tenement-houses themselves. That this can be done successfully, without financial loss, and with great sanitary and moral gain, has been amply demonstrated by the city of Glasgow.

Alcoholism, which is such a curse to our nation and which is indirectly a cause of the frequency of tuberculosis, will invariably diminish with the better housing of the poor. The honest laborer, who now, when he returns home, finds often dark, ill-smelling, dingy rooms, should be pardoned if he seeks occasional forgetfulness in the brightly lighted corner saloon. Give him a cheerful home, a wife who has been taught to cook a healthy, appetizing meal, and he will ten times rather remain home in the circle of his family, than go to the saloon and become intoxicated. In the money which is spent for alcohol instead of food, we often see the cause of underfeeding of our tenement population. The establishment of some place of amusement, where the laborer can go evenings and Sundays, alone or with his family, and there find healthful amusement and non-intoxicating drinks, offers another field of practical philanthropy.

The best place to cure the average, and particularly the poor, consumptive, is the sanatorium, but his Excellency the Governor has virtually called a halt to the establishment of such institutions. I think I could approximately estimate how many persons could be cured of the 15,000 who must now die from the disease, not because it is incurable, but because there are no places to cure it. If I were to give you the figures it would, indeed, be humiliating to our public conscience. I am full of hope that the resolutions which will be presented to this society will be unanimously adopted, and being sent to Albany, will cause a speedy repeal of the Goodsell-Bedell law, and that state-phthisiophobia at least will become unknown in New York.

What can we do to combat the ever-increasing private phthisiophobia? One word could answer that question, and that is *education*. Education of the adult and the child, of school teachers, employers and employees, by physicians, through health boards, societies for the prevention of tuberculosis, all aided by an intelligent and generous public press. Let the ways and means whereby the conscientious consumptive who takes care of his expectoration may become as safe an individual to associate with as anybody else, be known everywhere and to everybody; let it be known to the public that consumption is a preventable and curable disease, and that the earlier a consumptive submits himself to medical guidance and treatment, the greater are his chances for recovery; and let it be known that good food, plenty of pure and fresh air and a sober life are the most important factors in accomplishing this cure. Let the public be taught not to shun the consumptive, but to be helpful to him, so that he may have no occasion to hide his disease and thus become a secret source of infection. Let all those who can, financially or otherwise, help in the establishment of sanatoria for consumptive adults and tuberculous and scrofulous children.

Like an oasis in a desert was my privilege, a few months ago, at the occasion of the opening of the Stony Wolde Sanatorium for consumptive working girls and women, to listen to the words of a man converted from phthisiophobia to a stanch friend of the unfortunate consumptive. In explanation of the event let me state the following: This institution was called into life by Mrs. James E. Newcomb and Mrs. Geo. F. Shrady, both wives of leading physicians of this city, with the aid of a number of equally devoted philanthropic women from all classes of society, and who deserve our everlasting gratitude for the work they have done for their unfortunate sisters. Very near the sanatorium is the cottage of Dr. Newcomb, who with Mrs. Newcomb superintended the construction of the admirable institution. Because of the high standing of our converted friend and his great worth to the community, I know that I will be pardoned if, for the good of the cause, I quote in conclusion of my address his eloquent, generous, and chivalrous words.

They impressed my friend, Mr. Edward T. Devine of the Charity Organization Society and me so deeply that we wrote them down immediately after the closing of the ceremony, so as to be sure never to misquote them.

The Rt. Rev. Henry C. Potter, the Bishop of the Diocese of New York, at the opening ceremonies of the Stony Wolde Sanatorium, on September 15, 1903, in making the congratulatory address, closed with the following words: "I wish to make one statement, and I confess that I do it with a feeling of deep humiliation. As perhaps many of you know, I am interested in a summer home some seven miles from Raybrook. On learning that a State hospital for consumptives was to be established at that place, with many of my neighbors I began to protest. I have written minatory letters to the Governor on the subject. Dr. and Mrs. Newcomb have shown us here a different spirit. They have brought this sanatorium to their very home; they have built it within the shade of the camp in which they live. This teaches us again that we cannot help our fellowmen save as we are in personal touchwith them."

Let us hope that all those who are still afflicted with Federal, State, professional or private phthisiophobia, will follow the example of this good man, and become converted to friends of the consumptive and to helpers of a good and noble cause. the eradication of the "great white plague."

The following resolutions were submitted by the reader of the paper and seconded by Charles P. Blaney, Esq.; they were, according to the ruling, referred to the Board of Trustees for action:

Whereas, There exists a regrettable official and private phthisiophobia, and

Whereas, Through this exaggerated fear of the presence of consumptives untold sufferings are inflicted upon consumptive individuals and their families, and

Whereas, Recent attempts have been made to discriminate against the consumptive, not only on account of his physical infirmity, but also on account of his alleged mental and moral defects, and

Whereas, According to the opinion of the highest medical authorities on the subject of pulmonary tuberculosis there is among consumptives no greater tendency to immorality or crime than among other individuals, nor any ground for declaring the average consumptive to be inclined to brute selfishness, to loss of self-control and consequent distortion of the clearness of ethical perception, and

Whereas, Through the passage of the Goodsell-Bedell law, which was signed by Governor Odell at the close of the last session of the Legislature, it has been made impossible for any city in the State, or any fraternal order, charitable society, or philanthropic individual, to establish a sanatorium, hospital, camp, or other establishment for the treatment of consumptives, outside of the city limits, except under conditions which are practically prohibitive, and

Whereas, By Chapter 327 of the law of 1900, cities of the first class are authorized to erect sanatoria outside of the city limits, such action and the selection of a site to be subject to the approval of the State Board of Health, and by the same law hospitals and institutions, now, or hereafter established or maintained, are made subject to the approval of the local board of health, and

Whereas, Private property rights are sufficiently protected by general laws, and the process of injunction is open, in case it can be affirmatively shown that unwarranted injury would be inflicted by the establishment of a hospital on a particular site, and the necessity of obtaining the consent of the State Board of Health being an ample guarantee that a site shall not be selected which will threaten or unduly expose the health of any particular neighborhood, and

Whereas, It has been demonstrated in this country and in Europe that properly conducted sanatoria, hospitals, and camps for consumptives are not a danger to the neighborhood, and that such institutions are places where the consumptive poor receive a hygienic education and have the best possible chance to be cured and become again useful citizens and supporters of families, and

Whereas, There is at present a great deficiency of hospital accommodation in New York State for this class of patients, and

Whereas, Tuberculosis in insane asylums and prisons is becoming more and more frequent, and experience has demonstrated that through proper sanitation, proper treatment, isolation and agricultural colonies the death rate from tuberculosis in asylums and prisons can be greatly reduced, and

Whereas, The destruction of insanitary tenements and their replacement by model tenement-houses, the creation of parks and playgrounds, are most efficient general means to prevent the development of consumption in a community, Be it

Resolved, That the Society of Medical Jurisprudence, while convinced of the communicability of tuberculosis, and while urging all possible precautions against the spread of the disease by sputum and tuberculous food, is opposed to declaring tuberculosis officially as a dangerous contagious disease, and to its classification with smallpox, leprosy, and yellow fever. Be it further

Resolved, That the society is opposed to all measures by which needless hardship is imposed upon the consumptive individual, his family and his physician. Be it further

Resolved, That in accordance with the opinion expressed by the highest authorities on the subject of tuberculosis, this society does not think it just to state that among consumptives there should exist any greater tendency to immorality or crime than among other individuals, or that there is any ground for declaring the average consumptive to be inclined to brute selfishness, the loss of self-control, and the consequent distortion of the clearness of ethical perception. Be it further

Resolved, That in view of the great frequency of tuberculosis in insane asylums and prisons the Society of Medical Jurisprudence urges the respective authorities to inaugurate such sanitary, preventive, and therapeutic measures as will diminish the frequency of tuberculosis among the prisoners and insane. Be it further

Resolved, That the Society of Medical Jurisprudence urges the continuation of the work of the Health, Tenement-house, Park, and Street-cleaning Departments in improving the sanitary conditions, particularly those of our crowded tenement districts. Be it further

Resolved, That the Charity and Health Commissioners be enabled to establish and maintain sanatoria for the consumptive poor and those of moderate means, and that the building of model tenement-houses by private philanthropy or municipal enterprise should receive the greatest encouragement. Be it further

Resolved, That the Society of Medical Jurisprudence deeply deplores the Governor's action in signing the Goodsell-Bedell bill, and appeals most earnestly to His Excellency the Governor and the Legislature of the State for a repeal of this law, which, if it should remain on the statute books and be enforced, would involve the loss of thousands of lives and increase the spread of tuberculosis within the crowded districts of our cities and towns in an alarming degree. And be it further

Resolved, That copies of these resolutions be sent to the Treasury Department, the Surgeon-General of the Marine Hospital Service, to the Governor of the State of New York, and to the Speakers of the Senate and the House of Representatives at Albany, and to the medical and lay press, and that the President of the Society of Medical Jurisprudence also appoint a committee to take such steps as will bring the matter before the Legislature at the earliest possible date and cause a repeal of the unwise, inhumane, unjust, and cruel Goodsell-Bedell law.

16 West Ninety-fifth Street.

A Case of Trigeminal Neuralgia and Excision of the Gasserian Ganglion.—T. E. Gordon describes the case of a woman of sixty-three years who suffered such extreme pain from trigeminal neuralgia that she had attempted suicide. All her teeth were extracted in the vain hope of relief, and her life was made scarcely endurable by hypodermic injections of morphine. Removal of the Gasserian ganglion was decided on and the Horseley-Krause operation chosen. In this an opening is made in the temporal region of the skull; the brain and dura mater are together raised from the floor of the cranium as far as the points of exit of the second and third divisions of the fifth nerve; the space of Meckel is opened, thus exposing nerves and ganglion; finally the nerves are divided and the ganglion with its large sensory root removed. About eight months after the operation the patient was in good health and entirely free from her neuralgia. The scar was very slight, and the hair having grown, concealed the depression. The operation is a difficult one, and not unattended by danger, but it is encouraging to notice that there is a low mortality attending it.—*The Dublin Journal of Medical Science.*

THE DIAGNOSTIC SIGNIFICANCE OF CERTAIN REFLEXES AND TENDON-PHENOMENA.*

By H. OPPENHEIM, M.D.,
BERLIN.
PROFESSOR AT THE KLG. FRIEDRICH-WILHELMS-UNIVERSITÄT.

It is well known to you, gentlemen, that the testing of the tendon-phenomena and skin reflexes has attained increasing importance, from year to year, in the diagnosis of nervous diseases. Therefore, it may not be unwelcome to you to learn what I think of the value of such investigation based upon my own personal experience. I will essentially confine my remarks to the state of the tendon-phenomena and skin reflexes of the lower extremities.

First concerning the knee-phenomenon; it is certainly generally acknowledged, that the disappearance of this reflex represents a symptom of disease of the greatest importance. Especially for the reason that this is a reflex which is constantly present in healthy individuals. From my own experience in this connection, I desire to make the following statement: During the course of many years I have, nevertheless, known two or three individuals in whom from early youth this reflex could not be demonstrated. Once, in a markedly neuropathic individual with various anomalies in development—for instance, prognathism and syndactylism—I was compelled to assume that the absence of the knee-phenomenon was likewise considered an hereditary stigma degenerationis. In a second case in which the knee-phenomenon in mother and daughter could not be elicited, similar conditions were present.

On the other hand, there are individual cases which must be considered from a different standpoint; cases in which the knee-phenomenon in children of syphilitic parents is lacking, and which have the appearance as though the hereditary syphilitic contamination manifests itself exclusively in the deficiency of this reflex, without the necessity of other symptoms of hereditary lues being present. In such cases the thought always remains, that other symptoms of nervous diseases depending upon hereditary lues may develop in later life.

If you will consider the great number of individuals I have had occasion to examine in the course of time, concerning the state of the knee-phenomena, you will acknowledge that the very few exceptions only prove the rule, and you will accord me the right to say that the knee-phenomenon in healthy individuals almost never, hardly ever fails, and that we have in the deficiency of this reflex a symptom of the greatest worth in the recognition of diseased conditions. But there is one thing we should not forget: that there are pure mechanical conditions, which may render the demonstration of this reflex difficult or impossible. Obesity belongs in this category. The patellar tendon may be so buried in fat, that it may be impossible to percuss it and bring the muscle into contraction. Diseases of the knee-joint, characterized by swelling and deformity, or even a marked œdema, may have a similar effect. I remember two cases of advanced genuvalgum, in which the knee-phenomenon could not be elicited on account of the mechanical conditions. Lastly, there are certain individuals in whom the patellar tendon is very short and rigid, so that it is difficult or impossible to excite it, and in such a case you would again have a mechanical impediment, which could render the demonstration of this reflex impossible.

I will speak neither of the special importance of Westphal's symptom at the present time, nor concerning the exaggeration of the knee-phenomenon, but will at once consider another tendon reflex, viz., that of the Achilles tendon or, as I call it, the Fersenphaenomen (heel-phenomenon). As is well known, it consists in the fact that plantar flexion of the foot is brought about by percussion of the tendo Achillis. Notwithstanding the fact that this phenomenon had been known for a long time, it had never attained great importance in diagnosis, especially for the reason, that this reflex was believed to be quite inconstant in healthy individuals. This view could no longer be maintained when it became apparent that by a certain modification in the method of examination, namely, with the individual in a kneeling position, the reflex could be regularly elicited.

We must now say that the heel-phenomenon is a constant reflex in health. But if we were compelled to make certain exceptions concerning the constancy of the knee-phenomenon, the same holds good for the heel-phenomenon, though to a somewhat greater degree. This is true for the following reasons: Sciatic neuralgia, and especially sciatic neuritis, may, beyond a doubt, cause a disappearance of the heel-phenomenon. Moreover, sciatica is a widespread disorder. Nevertheless you might say it is a diseased condition. Naturally. But even after recovery from sciatica the heel-phenomenon may remain permanently absent. Since a great many persons have been affected with sciatica, you should not be surprised to find a number of otherwise healthy individuals in whom this reflex is absent on one side.

Further, the mechanical conditions, which may hinder the appearance of this reflex, play likewise an important rôle. The deformities of the foot, which are so frequent, particularly talipes valgus, may so influence the tonicity of the calf muscles or the tension of the Achilles tendon, that the reflex may be greatly weakened, or even rendered impossible. The frequently occurring traumatic and inflammatory affections of the ankle-joint may act in a similar manner. It also appears to me that a marked development of varicose veins has a tendency to weaken this reflex. Wherever none of the foregoing exceptions are present, you are permitted to consider the absence of the heel-phenomenon of great importance, and may depend upon this phenomenon, particularly in establishing a diagnosis of incipient tabes dorsalis, since according to recent observations, the heel-phenomenon may disappear a long time before the knee-phenomenon. But do not forget that alcoholism, diabetes, and other affections may likewise produce the same symptom.

Of the skin reflexes, the sole reflex has attained in our time an enormous importance, though it was formerly practically neglected. As is well known, it was through the efforts of Babinski that this reflex was given its diagnostic worth, in that by stroking the sole of the foot, he was able to differentiate between the movement of the foot and that of the toes. Formerly only the movement of the foot was essentially considered, and thereby, the fact that the movement of the toes was entirely different from that of the foot was overlooked. Under normal conditions, by stroking the sole, the foot is drawn backward—dorsal flexion, and the movement of the toes is that of plantar flexion. This is the new fact found by Babinski, upon which all else is based. It was further demonstrated that there are pathological conditions, under which, by

*An address delivered before the Anglo-American Medical Association, in Berlin, November 28, 1903. Translated into English by William W. Graves, M.D., St. Louis, Mo.

stroking the sole of the foot, a dorsal reflexion of all the toes, or especially of the great toe, is brought about. And thereby a diagnostic criterion was found of unusually great importance.

Nevertheless, it is not possible to condense into a law or formula the conditions under which this dorsal flexion occurs and which we now call Babinski's symptom. On the contrary, a number of conditions are involved which, however, intermingle to a certain degree.

First of all, we find Babinski's symptom in cases of spastic paraplegia of both spinal and cerebral origin, and especially in the former with greater regularity. The Babinski symptom would, therefore, appear to be a result of hypertonicity. But we will soon see that the law in this form is not fully true.

There are also conditions of hypotony and even of atony, of the leg muscles in which, in spite of the absence of tendon reflexes, Babinski's symptom is present. Then let us try to formulate another law. Babinski's phenomenon is a sign or a result of a lesion of the pyramidal tracts. In a general sense, at first sight, this seems to hold good. We find Babinski's symptom in affections which are characterized by either systematized or localized degeneration of the lateral pyramidal tracts. These conditions lead to the symptom complex of spastic paralysis, therefore, we might assume that Babinski's symptom is inseparable from spastic paralysis. But this is not the case. I have said before that it is also occasionally found in atonic conditions of the musculature. How is this to be explained?

There are affections which are not alone confined to the pyramidal tracts, but at the same time involve other areas of the nervous system, and thereby have an antagonistic influence on muscle tone. In this category belong the combined lateral and posterior sclerosis. Friedrich's disease and the combination of tabes dorsalis with hemiplegia. Under such conditions, the hypertonic influence brought about by degeneration of the pyramidal tracts can be fully compensated, an atony can develop, the tendon reflexes can fail, and of all the symptoms of disease of the pyramidal tracts only one remains—that of Babinski.

In a general way, the same holds good for a combination of anterior horn and pyramidal lateral tract affection or amyotrophic lateral sclerosis. Here, again, are two processes which oppose each other. Babinski's symptom may here likewise be the only symptom that indicates a degeneration of the pyramidal tracts, but this is by no means always the case.

When the pyramidal tract in the brain is involved, as in the usual form of hemiplegia, Babinski's symptom is, as a rule, present.

But it appears that coincidental lesions of certain cerebral tracts or areas may prevent the appearance of Babinski's symptom. Perhaps they are of certain tracts which originate in optic thalmus, tegmental motor tracts, perhaps lesions in central ganglia alone, perhaps of tracts which originate or end in the cerebellum, however we are still unable to make definite statements in this regard.

That Babinski's symptom is present in the first year of life is perfectly natural, because the child is born with undeveloped pyramidal tracts.

Assuming the law to be correct, that the presence of Babinski's symptom means a degeneration of the pyramidal tracts, are we always justified in concluding that Babinski's symptom indicates an anatomical change in the pyramidal tracts? No, not by any means. Because in epileptics, and after an epileptic attack, Babinski's symptom may occasonally be demonstrated. Inasmuch as there are other conditions under which this phenomenon appears, we do not always have the right, from the presence of this symptom alone, to conclude that an organic disease in the pyramidical tracts is present.

There is still another, though really obvious exception, to be mentioned. If through a peripheral disease or by a poliomyelitis the flexors for the toes are paralyzed, the normal reflex cannot take place, but instead, a dorsal flexion of the toes.

In conclusion, gentlemen, permit me to call your attention to a phenomenon which occupies a position very close to that of Babinski, and which was first observed and described by myself.

If, in a normal individual, on stroking the inner surface of the leg from above downward, with either the thumb or the handle of a percussion hammer, or by pinching a fold of skin on the inner surface of the leg, either no reflex movement will follow or a flexion of the toes will result.

Under pathological conditions—that is to say, in affections of the pyramidal tracts—instead of a plantar flexion of the toes, a dorsal flexion of the toes and foot is observed. This reflex differs from Babinski's, not alone in the point from which the reflex is brought about, but especially therein, that not only the extensor hallucis longus participates in the reflex movement, but likewise as constantly the tibialis anticus and often the extensor digitorum communis and the peronei. The contraction of the extensors for the foot is physiological when examining the plantar reflex, and the pathological reflex is only made known through the contraction of the extensors for the toes, whereas with the phenomenon found by me, the pathological reflex is more plainly indicated in that only under diseased conditions the extensors for the foot also contract, and especially the tibialis anticus. There are not a few cases in which the estimation of the toe reflex, according to Babinski, is uncertain, and it is just in such cases that the behavior of my reflex may prove decisive.

Diagnosis has been so advanced through the the establishing of both of these reflexes, that the so necessary differentiation between organic and functional nervous diseases is to-day no longer a difficult matter.

COMMENTARIES UPON LUES AND LEPROSY AS SUBCATABOLIC DISEASES.

By HOMER WAKEFIELD, M.D.

NEW YORK.

Lues.—Syphilis or lues is one of those diseases which while uncertain as to its exact etiology appears to be in abeyance to the strenuous efforts being made by an army of medical investigators in all civilized countries, and from all conceivable standpoints, to unveil the etiological mysteries of other diseases. Syphilis has in the past been the subject of much research and discussion as to its etiology, but all efforts having been without result, ambitious investigators have now turned to more fruitful fields. No parasite having ever been proved to be pathognomonic to the disease, and no clue to a more fruitful line of future research ever having been elicited, hopes have been blasted and interest has waned. It should be stated, however, that there are many bacteriologists and syphilographers who assume without supporting evidence that so serious and contagious a malady must be of parasitic origin.

Notwithstanding that there is as great a lack of evidence opposing the parasitic theory of origin

as there is supporting it, I have no hesitancy in emphasizing the statement that the manifestations of the disease are those of intense subcatabolism, and that the contagious virus may be aseptic, *i.e.* free from microorganisms, and entirely chemical in its pathogenic action, acting as an irritant, or as a virulent protoplasmic poison, opposing chemically the activity to normal catabolism.

A form of subcatabolism is thus the direct or acting cause of the syphilitic manifestations, and notwithstanding that gummatous tumors and ulcers do differ somewhat from other varieties, yet the same general processes, more or less modified by the peculiar nature of the poison, obtain.

The fact that toxins of bacteria *per se* are known to act largely as chemical poisons, and also that many drugs are known to act as subcatabolic agents, differing as they traverse certain channels and affect certain organs, proves conclusively that all of the manifestations of syphilis, and even of diseases of admitted bacteriological origin, may be due to chemical causes.

Perhaps no statement in my original paper on the "Pathology of Catabolism" caused more remark and adverse criticism than that in which syphilis was listed among the diseases of subcatabolism. Whatever be the theory of primary etiology that one may hold of syphilis, it must be borne in mind that its subcatabolic character can not be taken as a contradiction to it; for while catabolic stasis certainly predisposes to infection in all processes primarily of non-infectious causation, yet it must be admitted that also many processes primarily of infectious etiology may by mechanical or chemical irritation or other cause produce a typical subcatabolic condition or process.

That syphilis is a subcatabolic disease and follows a subcatabolic process is attested by the quite generally admitted fact that from the simple congestion to the inflammation, or hyperplasia, the acting cause is of an irritative character. The same is true of the gummata or syphilitic callosities, which by some observers are supposed to differ from the other manifestations; whether they are whitish or reddish-gray soft masses of intermixtures of gelatinous and fibrous tissues, something from wandering cells or hypertrophied connective tissue, none is excepted.

There is an undeniable analogy between gummata and the neoplasma of tuberculosis (phthisis, lupus), scrofula, and leprosy. The former diseases I have elsewhere analyzed and the latter I will follow with. Wagner[3] regards gumma as a specific new formation, in the same light that he regards all neoplasma. Lang[4] observes, "The gumma is thus a cellular new growth," though he follows, "I think it is better for clinicians to regard gumma as a *chronic* inflammatory process."

It has been suggested by Lang and others that "the contagium of syphilis retains its faculty of reproduction in healthy persons only for a certain time, probably coinciding with the time during which it may produce symptoms of irritation in the syphilitic subject. Since we find gummatous products in certain parts while in others there are yet only symptoms of irritation, we must explain the possible existence of infection by the assumption that it remains only in that part of the virus which has not yet lost its irritative property." The chancre is a "proliferation" of connective tissue of the skin and of the small vessels, which may be thickened to the point of their occlusion.

While it may be said that syphilis usually is typical to the extent of recognition, yet it occasionally differs so widely from the characteristics as to make it difficult of differentiation from other maladies of subcatabolism, producing similar lesions and degenerations. Syphilis may be said to differ principally from malignant growths in its greater degenerative activity combined with a much lessened general suboxidation, though it must be admitted that syphilitic manifestations may approach so closely to one or other of the many manifestations of subcatabolic conditions as to defy diagnostic distinction, except by being viewed together with coexisting lesions and conditions.

Tissues and blood cells having taken up the virus of syphilis, undergo a degradation from which they never recover. Those which become involved in the earlier toxicity undergo degeneration and thus give up their protoplasmic-held virus, to be again taken up by other cells. Finally, if the body survives the systemic reaction (the secondary manifestations), the attenuated virus is so distributed among the cells as to give partial or complete immunity, by virtue of the perpetuated virus-holdings of cellular protoplasm, acting as a toxic influence against newly acquired parasites, or as an "acclimatization" of the cells, and hence of the body as a whole, to the toxic influence of the virus; thus providing against or modifying the effect of newly acquired infection. Thus it is observed that the course of the primary and secondary reaction, the tertiary manifestations or the immunity attained, would not differ markedly, whether the virus were a bacterial product, or an organic venom, acting chemically or mechanically on the tissues, or whether the acquired immunity operated as a toxic, reacting upon the bacteria excreting it, or simply amounting to a cellular inurement to the attributes and activities peculiar to the virus.

The recent experimental expositions of agglutination, as I interpret them, display the reaction of cells to the irritative influence of heterogeneous substances, which so act only when cellular harmony and adaptation are impossible. As soon as acclimatization of the cells to the previously heterogeneous substances is attained they fail to cause irritation, although *per se* perhaps unchanged. Syphilitic manifestations, whether they be erosions, scleroses, papules, pustules, acne, ulcers, œdema, lymphadenitis, fever, roseola, pigmentation, leucoderma, alopecia, affections of the bones (decalcification), joints, muscles, sheaths, tendons, synovial sacs, etc., only present new combinations, arrangements and degrees of severity of some one or more of the manifestations of other subcatabolic diseases of non-specific characteristic. In progress, syphilis is very chronic in character. If it be sufficiently long continued in its ulcerated course, as would result from a long-continued irritation, carcinoma may, and does occasionally, occur.

In the blood, anæmia, chlorosis, leucocytosis, leukæmia, etc., occur as syphilitic manifestations as well as of benign affections.

Syphilis is second only to tuberculosis as a constitutional disease leading to amyloid degeneration.

Cachexia is produced in syphilis just as in other chronic affections, as a result of long-continued general systemic depravity. Pigmentation also occurs in the chronic sores of prolonged duration, in syphilis as in those of other processes.

The decalcification of bone and the lime redeposit (chaotic calcification) of gelatinized and putrefying tissues does not materially differ in syphilis from other chronic subcatabolic affections.

Rheumatic muscular pains accompanying the cutaneous eruptions of syphilis suggest the analogy to other processes displaying this symptom.

That syphilis is more general in its action and

manifestation than other processes most closely allied to it is universally evident.

Malignant, or galloping, syphilis, as characterized by increased disintegration, extensive ulceration or mortification, *nearly always* is accompanied by a marked depravity such as scrofula or tuberculosis, or still more frequently alcoholism, malaria, scorbutus or some other similar malady, which appears to add to the effect exerted by the specific irritating virus. Such is the case with the influences of traumatic, chemic and other injuries on the specific processes.

A development of a cheloid from the ecthyma pustules, and an evolution of the leucoplakia of syphilis into carcinoma have been reported.

During the irritative stage of syphilis, the lymphatic glands grow to tumors as large as or larger than an almond. Syphilitic eruptions have the same tenddencies to recur at the site of previous lesions, in scar tissue, as they do in cancers.

Whatever else can be said of the toxic virus of syphilis, it is certainly an agent that, when lodged in the protoplasm of the fixed and circulating cells of the body, acts powerfully as a retarder and perturber of catabolism, to such a degree that complete stasis followed by degeneration may be the result of the coincident action of any of the other causes of subcatabolism, namely, cold, fatigue, strain, traumatism, irritation, hyperacidity from gastrointestinal fermentation, ingestion of acid foods and beverages, suboxidation and deficient elimination of physiologic excretions. Any or all of these factors also acting singly or in concert will invariably aggravate syphilitic processes, and they in turn are aggravated by syphilis, as they are, one by another.

The specific virus is not sufficiently heterogeneous to the tissues of the lower animals to irritate them to the point of producing any of the manifestations characteristic of its toxicity in man. The same may be said of the toxin of leprosy, though this is known to be parasitic in man.

Leprosy.—My excuse for bringing the unusual disease of leprosy into the discussion of the pathology of catabolism is owing to the fact that it is the disease *par excellence* of extreme catabolic stasis. Leprosy, compared to other neoplastic diseases, is far the more general and universal in its action upon the human body, and in its two diverse forms, which are admittedly from the same bacterial origin, many *b* points set forth in my hypothesis of catabolic stasis are well illustrated.

The lepra bacillus of Hansen is very closely related to the tubercle bacillus of Koch; sufficiently so for one to be an evolutional product of the other. Certainly tuberculosis differs no more from tubercular leprosy than does the anæsthetic form of leprosy: that is accredited as a product of the same (lepra) bacillus.

The clinical lessons presented in the two diverse forms of leprosy are worthy of the profound consideration and reflection of medical philosophers. Both of the bacilli mentioned are decidedly saprophytic, for they can act only in degenerated tissue, the product of general or local subcatabolism. In the case of the ordinary tubercle bacillus, it is well known that a healthy person may be surrounded with them, they may inhabit the mouth and other cavities of the body without finding sustenance for pathogenic activity or procreation. Thus an individual may, while enjoying an active catabolism, give habitation to ordinary tubercle bacilli without suffering a pathogenic transgression. The same law applies to the lepra bacillus, only with much more pronounced manifestation, for infection of leprosy is much more easily traced than that of ordinary tuberculosis, and its horrible outbreak can be connected with the traced infections, entirely free from possible error. The lapse of from a few weeks to twenty or even thirty years may occur after infection, before conditions favorable to proliferation are developed.

A well-defined and highly illustrative case of this kind is that of a healthy European child of nine years, who became infected in Java, but did not manifest the disease until he was seventeen, while he was undergoing the vitiating life of a student in Holland, from which he returned to Java a confirmed leper, two years later.

Many individuals go through life without displaying a sign of the disease, after having for prolonged periods been exposed to all phases of infection, such as living among and having unrestricted communication with lepers in all stages and manifestations of the disease.

The other pathological rôle which is graphically portrayed by this disease is the radical variance between the manifestations of the two principal forms.

It is observed that accordingly as individuals are exposed to causative factors (of subcatabolism), as cold, fatigue, strain, worry, irritation, suboxidation, subelimination, gastrointestinal hyperacidity, etc., and it might be added accordingly as certain tissues of the body are determined to subcatabolic degeneration, the infection, course and progress of the disease are governed; and not by the intrinsic peculiarity of the microbe, except as to the general property of excretion of a toxin of great irritative power, and to the number of the bacilli involved, which governs the vicious cycle.

Accordingly as the body is subjected to the different causes of subcatabolism, the superficial or deep initiatory manifestations of the disease are determined. Wherever the primary degeneration of catabolic stasis is located, there the bacilli will become first established, and thus the tubercular or the anæsthetic varieties of the disease are predestined as typical vicious cycles. The former, a process attended with induration and hyperæmic reaction, exhibits a state of much better *general* oxidation, the catabolic stasis being more or less limited to the localized lesions, and surrounded by the indurated margin of intermediate and reactionary tissue. In the latter, however, the general oxidation is primarily at fault, indurations are rare or absent, and the degeneration is both widespread and in an advanced state.

It is of interest that in tissues in which oxidation is *normally* most active, the mal-chemistry is all the more pronounced when its dependent conditions become such as to inhibit it. This is well illustrated in the eye, which requires great oxidative activity for its functions, and is quick to manifest a crippled condition when its oxidative action is deficient. In the epithelia also we have *normally* great oxidase capacity and consequently a high degree of oxidation; but when any of the factors of oxidation are absent or lowered, it is very quick to undergo the degenerative metamorphosis, as is illustrated in normal milk "secretion" and in many pathogenic processes characterized by colloidation and putrefaction. The nucleonic substance of the nervous system also is no exception to the above rule, and when great general subcatabolism is present, as in leprosy, its degeneration is rapid, and to this is largely due the anæsthesia of that form of the disease which is identified with it.

The influence of inhibited circulation of blood upon sensation is of great interest in this connection. Anæsthesia may be produced, by arresting circula-

tion in a part, too rapidly to admit of its acting by interfering with nutrition, hence we may, by exclusion, deduce that it must be due to the arrest of cellular respiration (oxidation.)

Accordingly as we retard circulation, a tingling sensation, numbness, or complete anæsthesia may be produced. These manifestations are observed as blood-vessels are occluded by degenerate, colloid and other tissue detritus, by thrombi, emboli, and by pressure, etc.

Especially noteworthy in this connection is the local anæsthesia produced by injecting a circumscribed area of tissue with sterilized water, when by perfect distension of the part, the circulation is arrested so completely that the area is blanched and the anæsthesia will permit of any kind of a surgical, or other otherwise painful, operation.

While all active causes of suboxidation may be the predisposing factors of leprosy, yet there are two which are perhaps more important than the others, namely, narcotic habits and the hot rays of a tropical sun together with an excess of water vapor in the atmosphere.

How the excessive red rays of a tropical sun retard catabolism is explained by their degradation of the blue and ultraviolet rays which promote oxidation. And the approach to dyspnœa of humid atmospheres, with its train of suboxidation events, is capable of two explanations: firstly, that the oxygen of the air suffers dilution by the unrespirable water vapor, and secondly, that the percentage of oxygen of the air is lessened by new combinations of free oxygen with an excess of hydrogen, forming water in the lungs. It has never to my knowledge been determined by experiment, whether the deficiency of oxygenation of humid atmospheres is due to simple dilution or to the formation of water in the alveola.

No true student of tropical maladies will fail to recognize as a factor in the etiology of leprosy, and in particular of the sluggish anæsthetic form, that general disposition of such climates to relaxation, lassitude, lethargy, torpor, and with it all extreme sedentation.

It is observed that a large number of persons who came in contact with leprosy during childhood, without contracting the disease, but who did contract it years afterward, far removed from leper communities, did so generally during the adolescent period, or (in women) when debilitated by marital relations, pregnancy, parturition, or lactation. It is noted that women in general acquire the necessary catabolic stasis after marriage; during which the long sterile lepra bacillæ become virulent, thus developing the vicious cycle of leprosy.

The disposition to excessive ulceration and sloughing off of the extremities is due to the colloidal infiltration and obstruction of the vascular system, and the maximum effect of the consequent suboxygenation, and suboxidation occurs at the extremities; hence the extreme subcatabolism in these regions.

If the bacilli attain great virulence on the surface, the skin or membranes, macules and nodules appear and the so-called tubercle form presents. However, if the bacilli gain entrance to the general circulation it is characterized by irritative, atrophic changes in the nervous tissues and the so-called anæsthetic form of leprosy manifests itself. This is simply an observed relation and does not evince which element precedes, the subcatabolism or the parasite that must be deduced from the total evidence.

I have already set forth my analysis of the action of the elements of nervous structures (the nucleins) upon oxidation [8b]. I have pointed out why such tissues of easy digestibility atrophy instead of hypertrophy, when exposed to irritation and other accidents of similar import, and why catabolism would fail and general sluggishness and putrefactive degeneration ensue, as a result of disorganization and atrophy of oxidase, and the consequent subcatabolism. In this respect the anæsthetic form bears the most marked contrast to the tubercular form, in that the former presents the most characteristic picture of the extreme form of subcatabolic degeneration.

Anæsthetic leprosy also presents the best-defined illustration of the progress of diseases of catabolic stasis, and while it is decidedly atypical, its slow and prolonged course permits of a very elucidative observation of its several stages.

The site of ingress of the bacilli is not by any means the sole determining cause of the peculiarities of the two principal forms. I have mentioned that those tissues which by previous vicissitudes have become subcatabolized, constitute the tissues involved and the avenues of extension. The extent of their degeneration as well as the nature of the involved tissues exerts a powerful influence over the progress of the disease. The superficial form (tubercular leprosy) appears invariably to offer the most favorable media for the multiplication of the bacilli, and this fact alone serves as a modifying influence upon the activity of the disease, because of the hyperæmia so caused; the hyperæmia in turn being in part at least responsible for the fibrosis and sclerosis.

Accordingly as the nervous structures are invaded and destroyed and the circulatory system of the body becomes clogged with tissue detritus, the circulation becomes impeded, and from a combining of this and a degeneration of the heart muscle, oxygenation of the tissues is interfered with; and whether the tubercular form has preceded or not, the entire body sinks into that subcatabolic depravity which is known as the anæsthetic form. With the development of this form either primarily or secondarily, inasmuch as the lepræ bacilli become attenuated to an extent, often, that they are scarcely in evidence, it would appear that they have suffered suboxidation or tissue putrefactive toxæmia, and the disease progresses thence along a course, far more characteristic of subcatabolism than of that of the bacillus of Hansen. There is good reason to believe that if Hansen's bacillus could be eliminated from an anæsthetic leper, his disease would progress just the same. It is evident that the lepra bacillus is a saprophyte dependent for sustenance upon gelatiniform or putrid organic matter. It thrives best among slovenly people, and among such it finds succor both in the environment and upon the person of man.

Communities in which general slovenliness is universal, where persons seldom bathe the whole or any part of the body, where personal and bed clothing is never washed, but is passed from one to another generation, the bacilli thrive, and when they gain access to the sebaceous and sudoriferous glands of the skin, they find an abundance of putrid excretions occluding the ducts, into which they resort.

It is impossible to transmit leprosy to a perfectly healthy, hygienic person, even by inoculation, as has been proved by Danielson,[8] yet many cases are on record in which individuals have acquired leprosy by inoculation as well as by much less formidable methods. If the inoculation be accompanied by sources of irritation, such as will produce subcatabolism of the part, before the death or excretion of the bacillus, then a favorable condition may be

produced for the propagation of the parasite; otherwise it fails and finally dies.

The races most afflicted by leprosy are addicted to vices and I have no doubt that narcotic habits and excessive venery play a part in the production of susceptibility. Both are active producers of general subcatabolism. The fact that lepers quite generally attribute their original infections to "colds," and the causes of ulcers to traumatisms, is significant to students of catabolism.

One factor of subcatabolism, identified as a cause of leprosy, is chill, damp abodes, either in moist, cold, or humid, hot climates. Dry climates of all temperatures are most immune, which is universally the case with all diseases of subcatabolism. I directed attention to the importance of differentiating between moist and dry temperatures in 1901, in connection with cardiotherapy.[8a]

The hyperæmic state, the roseola of leprosy, are not unlike those of syphilis, while the leucoderma and pigmentations are histologically not unlike those complicating cancer. The thickenings, fibrosis and sclerosis suggest the same causative factors at work as in other diseases, only in different orders and degrees. Alopecia, as is well known, is a complication of typhoid fever, syphilis, and many scalp affections.

The tubercles of leprosy show a greater tendency to ulcerate and putrefy than those of tuberculosis. "In many cases the neoplasm undergoes a sort of fibroid degeneration. . . . The ulcerative process varies accordingly as the necrobiosis involves the center or the totality of the tubercle" (Morrow).[6] This attribute of ulceration I have called attention to in neoplasms of malignant type.

The site of ulceration on the lower extremities is marked by a well-defined œdematous infiltration which we observe often, though less pronounced, in simple ulcerations. A swelling precedes the ulceration. During the course of the tubercle form, ulcerous tissues rapidly heal, while tissues suffering the anæsthetic form heal with difficulty. The course and character of the ulceration of leprosy, like the most malignant courses of cancer, are determined by situation as regards exposure to air, and by intercurrent inflammations involving hyperæmia and better oxidation of the tissues.

Erysipelas when occurring on lepers has been observed markedly to improve and even cure the leprosy, yet Coley's toxins[1] have failed to accomplish what has, by the active, mechanical irritative effect of the virulent bacilli, been achieved. Leloir[4] has observed in cases of association of the anæsthetic with old cases of the tubercle form that the integument, subcutaneous tissues, and the muscles of the face, have acquired a gellatiniform colloid degeneration, of the consistency of trembling jelly. Leloir[5] has remarked of having been struck by the enormous number of persons affected by scrofula, tuberculosis, anæmia, and chlorosis in the leprous regions in Norway, which he visited. He observed that the coincidence of the scrofulous diathesis disposes the leprosy to partake of a scorbutic appearance. Leprosy occurs very often in persons of scrofulous and tuberculous antecedents. The coincidence of leprosy and pulmonary phthisis has been often noted in families.

Leloir[5] has been impressed with the remarkable coincidence of goiter and leprosy in Italy. The coexistence of goiter and of diffuse and œdematous infiltrations of leprosy has suggested the use of thyroid extract, and it has been found of limited value in a class of cases, probably when the thyroid gland suffered leprous involvement.

The excessive dissolution of the more highly digestible tissues, coupled with their suboxidation, is, as in gout and other analogous diseases, responsible for a dearth of tissue detritus in the circulatory fluids of the body, which, taken together with some other symptoms which have been mistaken for plethora, have led to the erroneous diagnosis of this condition and to the practice of venesection in a class of patients already almost too weak to walk.

Conclusion.—I wish to close this brief comment on syphilis and leprosy by directing attention to the fact that in their therapeutics, parasiticides, *per se*, however powerful, unless they are also active oxidants, are of no value whatever, and conversely oxidants, if active, are of the greatest value even if devoid of parasiticide properties. Moreover, mercury, in the primary stage of syphilis, does not even destroy the virus, as is attested by the later appearance of the secondary and tertiary manifestations. The iodide of potassium accomplishes a similar purpose as an oxidant in syphilis, leprosy and in cancer, though it is most valuable in the former. All manner of agents producing hyperæmia of the tissues have been found of the greatest value. Erysipelas has been mentioned: the bites of venomous serpents, scorpions, hornets, etc., when not proving fatal, are even curative; which suggests the hyperdermic injections of attenuated venoms, to the same end. Hot baths, exercise, cardiac stimulants, oil massage, using the oil of highest reduction (oxidation) power, chaulmoogra oil, perhaps, and oil internally, which has been found so efficient in leprosy (though I would commend that it be phosphorized to enhance its superficial oxidative value), have all been found of value. Theoretically, an arrangement by which Röntgen or ultraviolet rays of light, or still better, high-frequency currents, could be administered to the entire body for long periods daily, would be most efficacious; yet it must be impressed upon the reader that several of these agencies must be harmoniously combined to attain the best results in a given case.

The rational basis of treatment, however, must be the accomplishment of the one end, namely, the restoration of normal catabolism and the combustion and elimination of the accumulated and decaying refuse of past subcatabolism, and not any attempt at independent parasitic destruction.

Relative Consumption of Whiskey and Beer.—In sixty years the annual per capita consumption of whiskey has gradually decreased from two and a half to one and a quarter gallons. In forty years the consumption of beer has increased from less than two to more than seventeen gallons per capita.

DIAGNOSIS OF ACUTE LOBAR PNEUMONIA.

By STEPHEN SMITH BURT, A.M., M.D.,

PROFESSOR OF MEDICINE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In arriving at a diagnosis of acute lobar pneumonia we have to consider the previous history of the patient, the symptoms, the physical signs, and the points of differentiation. The customary history related by a patient with this affection is of some recent unwonted exposure to cold or to a wetting, which, however, in the light of our present knowledge, is simply the final act in the destruction of the natural barriers to infection. Preceding this exposure, there may have been noticed a variable period of debility, yet oftentimes no account is given of a prior indisposition. Nevertheless, in my opinion, a predisposing cause other than the mere chilling of the surface, which in itself is not generally sufficient, already must have been established. It has long been my conviction that whoever is in a perfect physical condition, which means power of resistance unimpaired, is practically exempt from pneumonia. But this subject pertains more especially to the etiology of the disease, and has been discussed by me at some length in a former dissertation.

A typical case of acute lobar pneumonia begins with a severe chill of considerable duration. There is fever even during the chill and the fever rapidly rises to a high elevation. With this there are headache, loss of appetite, and general pain and discomfort. After a few hours the patient is taken with a sharp stitch in the side, a short painful cough, and rapid, shallow, catching respiration. The face is flushed; sometimes the flush is confined to one cheek, and then the reddening is often on the side corresponding to the pneumonia. The position, when in bed, is upon the back or else upon the side which is affected. Herpes may appear upon the lips, and also on the cheeks, nose, eyelids, and on the body elsewhere. The expectoration is at first frothy mucous, then a clear, viscid material, scanty and difficult of expulsion. Later it is more or less tinged with blood, somewhat less tenacious, and more abundant. It varies from a faint lemon to a dark brickdust color, and is known as the rusty sputum of pneumonia.

This peculiar reddish, semi-gelatinous, substance, appearing in small discrete masses, each surrounded by a zone of frothy mucous, and sticking to the bottom of the receptacle, is one of the distinctive features of a pulmonary inflammation. Exceptionally, there is blood-streaked sputum, and even clear hemorrhage. When the expectoration is dark brown in color and confluent, it is considered an unfavorable indication. The temperature rises in a few hours to 104° or 105° F., and maintains a high elevation to the end of a week or ten days with but slight daily fluctuations. It then, as a rule, rapidly falls to or below the normal standard. The pulse, which is full and tense, ranges from 100 to 120 in frequency; the respiration is increased from 30 to 40 per minute. The tongue is coated white and furred, and in severe cases, becomes dry and brown; the bowels are usually constipated, and the quantity of the urine is diminished. With characteristic symptoms of pneumonia the physical signs are apt to be equally well-marked, and under these circumstances, the disease commonly is diagnosticated. But idiopathic, secondary, and also terminal pneumonias may occur with few, if any, outward indications. When such is the case, physical examination is liable to be neglected and the condition of the lungs thereby is overlooked. Although the initiatory chill is one of the most constant events in pneumonia, it may be absent nevertheless, and sometimes in adults, as well as in children, there will be no cough, no pain, and no expectoration. There may be simply a moderate increase of the temperature and pulse and respiration. Rapidity of the breathing alone in a patient lying quietly in bed is a suspicious circumstance. The temperature may not be above 102° or 103° F.; the pulse may not exceed 90 or the respiration 30 per minute. The cheeks may be pale instead of flushed. Herpes is not a constant manifestation. In very old persons occasionally there is no elevation of temperature. While rapid devervescence of a few hours duration in the nature of a crisis is the rule in pneumonia, the decline of the fever is not infrequently by lysis, which, in other words, is gradual and prolonged. This disease is especially prone to latency in alcoholic patients. Secondary pneumonia, which occurs in such maladies as typhoid and typhus fevers, diphtheria, rheumatism, and influenza, may give rise to no symptoms that can be distinguished from those of the disease with which it is associated. Likewise with terminal pneumonia, which so frequently closes the scene in chronic diseases of the heart, the lungs, the kidneys, in diabetes mellitus, and in malignant affections. It is important, therefore, as a routine practice, always carefully to explore the chests of all patients under observation in which there is even a remote possibility of an idiopathic, intercurrent, or a terminal pneumonia. In fact, nothing but the frequent observance of this precaution will save the attending physician from the surprise and mortification of being confronted at a necropsy, sooner or later, with the evidences of a pneumonia previously unsuspected.

Consolidation occurs anywhere in the lungs from the base to the apex, and from the center to the circumference. Wherever begun it may spread through part of the lobe, the whole lobe, or practically the entire lung. It may involve both lungs in varying degrees simultaneously. Inspection of the patient reveals either a picture of the disease that is unmistakable or else nothing which is especially characteristic. Rapid and possibly difficult breathing with inspiratory dilation of the nostrils are seen, attended by marked activity of the accessory muscles of respiration. Meantime, the affected side will be restricted as much as possible in its movements. The apical impulse of the heart is about in its normal position. There is generally no visible enlargement of the side involved, yet mensuration may show a slight increase in its semi-circumference. On palpation vocal fremitus over the solidified lung is usually exaggerated. In so-called massive pneumonia, in which the exudation fills the bronchial tubes, and where a thick deposit of fibrin, or a fluid effusion, covers the lung, this vibration of the voice is not appreciable. The immobility of the affected side is confirmed on palpation; also the fact that the heart is not materially displaced. On percussion there will be varying degrees, at times modified by a tympanitic note, up to complete dulness wherever there is consolidation. Flatness, which predicates an entire absence of a pulmonary quality, is not developed in pneumonia unless there is an exudation also into the larger bronchi, a considerable pleurisy, or else the greater part of the lung is solidified. In central pneumonia, if the lesion fails eventually to reach the surface, no abnormal resonance is likely to be developed. Sometimes, owing to exceeding stoutness neither dulness nor other physical signs can be demonstrated. Still, ordinarily, under these conditions, with fever preceded by a marked rigor, and associated with rapid breathing, and the peculiar pneumonic sputa,

diagnosis should be made notwithstanding. By means of auscultation we find, if the patient is seen early enough, a decrease in the intensity of the breathing in the region involved. Later there may be heard close under the ear a multitude of fine dry crackling sounds at or near the end of inspiration. These sounds, known as crepitant râles, undoubtedly are produced in the pleura. Frequently, they are not developed unless the patient is made to take a deep inspiration. Hepatization of the lung is accompanied by bronchial or tubular breathing. Meantime crepitant râles may remain audible in the immediate neighborhood. Exceptionally bronchial breathing appears without râles of any kind, and likewise without râles disappears with the absorption of the exudation. The kind of breathing heard through solidified lung is like that which is audible in health over the lower end of the trachea and its bifurcation. This normal bronchial breathing may have an unusually wide diffusion into the surrounding pulmonary tissue, and, unless care is exercised by the examiner, it may be mistaken for a sign of consolidation. The voice transmitted through the lung where there is solidification is known as bronchophony. It may have a peculiar bleating quality which is called ægophony. Central pneumonia and small areas of hepatized lung in various situations that otherwise might be overlooked, often can be detected by a bronchial whiff, which is generated only by and during an enforced cough on the part of the person under examination. All the negative conditions for bronchial breathing may exist, but if the patient will not or cannot breath deeply, from fear of pain or from exhaustion, the bronchial quality will be either feeble or else undeveloped. When the larger bronchi are filled by an exudation, such as occurs in massive pneumonia, there will be no bronchial respiration. Resolution of the products of inflammation is attended by the gradual disappearance of bronchial breathing as well as by dulness and the various other signs of pneumonia, though the dulness may remain in a moderate degree indefinitely. The bronchial resolves itself into bronchovesicular and thence into vesicular respiration, during which process and for a variable period afterward are heard large and small mucous râles, together with fine crepitation. The heart sounds in pneumonia are generally well-defined and the pulmonary second sound usually is accentuated. If the right side of the heart is giving out, which is caused by infectious degeneration and increased pressure in the lesser blood circuit, the accent upon the pulmonary second sound will disappear. When the entire heart is failing in strength, all the sounds become weak, and, losing their muscular element, valvular in character. The urine in pneumonia is commonly acid in reaction, of high specific gravity, and it may contain hyaline, granular, and epithelial casts, together with traces of albumin. Indican may be in excess. Urea and uric acid are variable in amount. The chlorides are diminished. This decrease in the chlorides of the urine is a striking feature of pneumonia. Microscopical examination of the expectoration as a rule reveals the diplococcus pneumoniæ of Fraenkel and Weichselbaum. And, inasmuch as pneumonia is a constitutional as well as a local infection, this organism has been found also in the living blood, where in future, with improved technique, it will probably be looked for with regularity, just as we now seek for the plasmodium in malarial affections. The demonstration of the diploccus pneumoniæ in the general circulation will be of diagnostic value, especially where the pulmonary signs are indefinite and there is no expectoration. A blood count ordinarily shows an inflammatory leucocytosis. Increase of the white corpuscles occurs within a few hours after the chill, and amounts to 12, 20, and even 60,000 cells per cubic millimeter. With a slight decline after the first twenty-four hours, this increase remains comparatively great until the advent of defervescence. A definite parallelism between the degree of leucocytosis and the extent of the pulmonary exudation has not yet been positively established. Nor has an exact correspondence been shown to exist between the amount of leucocytosis and the grade of the infection. The mildest and the most severe infections have been known to occur without leucocytosis. Among six cases of pneumonia with moderate infection but of extensive solidification recently under my care, only two had more than nine thousand white blood cells per cubic millimeter, and all eventually recovered. Consequently, the general condition of the patient, in connection with the cardiac and pulmonary signs, is a more reliable guide in regard to the gravity of the situation than the degree of the leucocytosis.

In deciding between pneumonia and typhoid fever a marked increase in the number of white blood corpuscles would be in favor of pneumonia. Distinction between acute tuberculous pneumonia and simple acute lobar pneumonia, which formerly depended almost entirely upon subsequent events, can now be made with much less delay by the microscopical examination of the expectoration. Tubercle bacilli are found in the sputum of acute tuberculous pneumonia before the physical signs of local softening are demonstrable. For example, a case not long ago came under my care which, so far as physical signs and symptoms were concerned, was apparently simple acute pneumonia, but certain suspicious facts in the history led to a search for the tubercle bacilli in the sputum, and they were found in abundance, whereby it was settled much earlier than formerly was possible that we were dealing with acute tuberculous pneumonia or acute pneumonic phthisis. Further developments confirmed the finding of the microscope. There is often danger in children of confusing the cerebral symptoms of pneumonia with those of meningitis. An examination of the chest, which ought never to be neglected, should reveal the presence of the pneumonia; moreover, in tuberculous meningitis there will be a normal or a subnormal leucocyte count, while commonly there is leucocytosis in pneumonia. It is sometimes difficult to decide in adults as well as in children between pneumonia and pleurisy with effusion. This latter affection may begin with all the usual symptoms of pneumonia, though commonly they are less pronounced. In pleurisy the fever may be intense at the start, but, instead of maintaining its intensity, as in pneumonia, it rapidly declines and gradually disappears. There is nothing like the peculiar rusty sputum of pneumonia in pleurisy. Nor is there any such decrease of chlorides in the urine of the last named disease as there is in pneumonia. On examination of the chest there is a lack of mobility of the side involved in both affections. There may be in pleurisy a decided enlargement of this side, whereas in pneumonia enlargement is almost imperceptible. The heart is pushed toward the side away from an effusion; it is not materially displaced by a consolidation. Vocal fremitus is absent almost invariably in pleurisy, while it is always present in pneumonia if not exaggerated. The existence of this vibration of the voice as appreciated by the hand in the one, and its entire

absence in the other disease, is a valuable point of differentiation. It is important, however, to remember that a person with a naturally weak voice, or with an acquired aphonia, will develop neither vocal fremitous nor resonance under any circumstances.

Upon percussion in pleurisy there is flatness over the fluid from the dependent part of the chest upward; in pneumonia, there is dulness, irrespective of posture, wherever there is consolidation. The flatness of pleurisy, unless there is a very large effusion, changes in position with the patient's movements. If sitting, the resonance may be normal in the infraclavicular region, or dull, or else possibly tympanitic, but when lying face downward there will be flatness. Exceptionally there will be flatness in this region when the patient is sitting, and tympanitic resonance when lying upon the back. The dulness of pneumonia, on the other hand, as previously mentioned, maintains its position in the chest regardless of changes in the attitude. There is a resistance to the percussion stroke over fluid which to an experienced examiner is quite distinct from that over a consolidation. Traube's semi-lunar space of tympanitic resonance, which is bounded by the liver, the lower border of the left lung, the spleen, and the left costal arch, is obliterated by an effusion in the left pleural cavity, whereas the peculiar hollow sound of the stomach in this locality remains unaffected by pulmonary hepatization. Vocal resonance is diminished, though seldom absent in pleurisy, and present in pneumonia if not intensified. When there are crepitant râles on auscultation in pneumonia there is commonly coarse friction in pleurisy. In pneumonia the respiration becomes sharply defined and bronchial; in pleurisy, it is either feeble, absent, or else faintly bronchial in character; heard as from a distance and as if muffled in the one it is close under the ear and distinct in the other instance. Sometimes, however, the breathing is as strongly tubular in pleurisy as in pneumonia, not only with children, in whom it is more often found, but also with adults, and especially in the infraclavicular region. But perplexing as this problem at times may be, it should not often require for its solution an exploratory aspiration. The use of the hypodermic needle wherewith to decide between a fluid effusion and a solidification, except upon rare occasions, to say the least, is unnecessary. To determine the nature of the fluid, however, it is indispensable. If an examiner with a fairly acute ear and delicate sense of touch will gently percuss over the region in question, with the tips of the fingers so as not to develop extraneous collateral resonance, there will be found, generally without difficulty, both flatness and its peculiar resistance. Moreover, this flatness will extend in large effusions, unlike the dulness of pneumonia, beyond the edge of the sternum of the affected side, and, with fluid in the left pleural cavity, down into the Traube's semi-lunar space of tympanitic resonance. Furthermore, there is the dislocation of the heart referred to above, and, if the effusion is in the right side, also a possible depression of the liver, neither of which is found in pneumonia. As there is generally a large amount of fluid where the bronchial breathing most resembles that of pneumonia, there is little room left for a change in the level of flatness with an alteration of the position of the patient. Vocal resonance is diminished and vocal fremitus is absent, at least in adults with pleurisy, as already described.

Finally, bearing in mind that the right in health usually transmits sound more than the left side, there may be an increase in pleurisy anywhere from half an inch to an inch and a half in semi-circumference, whereas in pneumonia the enlargement, if present, is insignificant.

115 East Thirty-fourth Street.

The Sign of the Orbicularis in Peripheral Facial Paralysis.—George N. Jacoby says that it has long been assumed that the upper facial nerve was not involved in hemiplegia. This is now known to be a mistake, and the recognition of the error is due in great part to the sign of the orbicularis. The symptom consists in the inability of a hemiplegic voluntarily to close the eye upon the paralyzed side, except in conjunction with the other eye. The author thus summarizes his study of the subject: (1) The statement of Bard that the sign is invariably lacking in peripheral facial paralysis and is, therefore, a distinguishing mark of central affection, is incorrect. (2) The presence of the sign in peripheral paralysis is further proof of the existence of commissural fibers between the nuclei of the seventh nerves. (3) The sign is of clinical value as far as its presence in peripheral paralysis shows that complete recovery has not occurred. (4) The secondary over-action in the orbicularis palpebrarum, which is late in appearance and always coincides with some recovery in power, does not occur in those cases in which the sign, having been present, has passed away.—*Journal of Nervous and Mental Diseases.*

Bacteriology of Middle Ear Suppuration.—Wyatt Wingrave has microscopically examined the discharge from one hundred cases of middle ear suppuration, and analyzes the results with special reference to the presence of tubercle and "acid-fast" bacilli. His conclusions are as follows: Acid- and alcohol-fast bacilli are demonstrable in a large proportion of cases of chronic purulent ear discharge. In seventeen cases they were presumably tubercle bacilli, in so far that they conformed to the recognized morphological and staining characters, and were for the most part associated with reliable clinical evidence of tuberculosis. In seven (pseudo-tubercle bacilli) cases, while conforming in a greater or less degree to the staining requirements, they were morphologically unlike tubercle bacilli, yet five of the patients had either a family or personal history of phthisis. Success in their demonstration in any great measure depends upon the methods of collecting and staining together with perseverance in search. In the peculiar selective action of the squamæ in retaining the carbol fuchsin—a property specially attributed to certain bacilli—we have at once a possible source of error in diagnosis and an explanation of the peculiar affinity of other bacilli for fuchsin.—*Annals of Otology, Rhinology, and Laryngology.*

Pneumococcic Arthritis: Report of Three Cases.—Campbell P. Howard reports these cases. That lobar pneumonia is an acute general infection, and not a purely local disease of the lungs, the author states, has long since been established beyond all dispute. But he thinks that still further evidence may prove of interest. The first case affords a good illustration of septicemia from Fraenkel's pneumococcus without marked pulmonary involvement. The clinical summary is as follows: Acute lobar pneumonia, right mid-lobe; acute pericarditis (seventh day); arthritis of the right shoulder (seventh day); acute vegetative endocarditis (eighth day); meningitis (ninth day); arthritis of the right ankle (tenth day); death (eleventh day). The organism isolated from the blood and that from the ankle-joint were run through the various media, and showed typical growth. In the case of the second patient, the left shoulder and right knee-joint contained large quantities of purulent fluid. Smears showed capsulated diplococci. In the case of the third patient, the pneumonic consolidation involved only a small area on the apex of the upper right lobe. The smears from the mitral vegetation and joint fluid showed the presence of typical lanceolate diplococci.—*Bulletin of the Johns Hopkins Hospital.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE CARE OF MILK AS A FOOD FOR INFANTS.

THAT milk is, under almost all conditions, the best form of food for infants is almost universally agreed, and, as a rule, mother's milk is preferable to cow's milk. As to methods of preparing milk, by sterilization, by pasteurization, by refrigeration, by dilution, by addition, there is, however, less universal agreement. It will be recognized by all practitioners that a variety of factors enter into the decision. On the one hand, there will be found children who thrive in the absence of all dietetic precautions, while, on the other hand, there are children who fail notwithstanding the greatest care with respect to the character and the preparation of their food. The factors underlying such contrariety of result must reside in part within the individual, in part within the milk used as food. One aspect of this subject has received consideration in the course of an investigation undertaken by Drs. Wm. H. Parke and L. Emmett Holt (*Archives of Pediatrics*, December, 1903, p. 881) into the production, transportation, and feeding of cow's milk in New York City, and extending over a period of two years. The following objects were had in view: (1) a comparison of the results of infant-feeding in tenements in summer and in winter; (2) a determination of the influence upon the results exerted by the character of the milk used, especially its original bacterial count, its preparation, and whether heated or not; (3) and of other factors, such as the care of the infants and the surroundings to which they were exposed.

Satisfactory observations were made and records obtained in 632 cases. The children were studied in small groups, not exceeding fifty, principally at their homes, and the existing conditions being left unchanged. Clinical study and bacteriological investigation were carried on jointly, in order to determine whether any relationship existed between the number and the character of the microorganisms present in the milk and the amount of diarrhœal disease in the children using the milk. As a result of the observations made, the opinion was formed that the most important factor in securing good results is intelligent care. This applies to bottles and nipples, to methods of feeding, quantities, frequency, withdrawal on the development of diarrhœa, etc., the milk itself in the house, methods of sterilizing, clothing and cleanliness and fresh air. The results, in general, were found to be much less affected by the character of the milk than had been anticipated and distinctly less than by the sort of care the infants received. The surroundings alone, also, had less influence than anticipated. The depressing effects of great atmospheric heat, 90° F. or over, were marked, apart from the character of the food. A bad method of feeding, or feeding without any method, was responsible for bad results when the milk itself was of good quality. Comparatively little appeared to be accomplished by the distribution of printed slips of directions, partly in consequence of ignorance, partly in consequence of stupidity, unless supplemented by personal explanation.

It was found that during cool weather neither the mortality nor the health of the infants was appreciably affected by the kind of milk or the number of contained bacteria. The different grades of milk varied much less in the amount of bacterial contamination in winter than in summer. During hot weather, when the resistance of the children was lowered, the kind of milk taken influenced both the amount of illness and the mortality. Those who used condensed milk and cheap store-milk did the worst, while those who received breast-milk, pure bottle-milk, and modified milk did the best. The effect of bacterial contamination was marked when the milk was taken without previous heating, but unless the contamination was excessive the effect was only slight when heating was employed shortly before feeding. The number of bacteria that may accumulate before milk becomes noticeably harmful to the average infant in summer differs with the nature of the bacteria present, the age of the milk, and the temperature at which it has been kept. When milk is taken raw, the smaller the number of bacteria present the better are the results. Heat above 170° F. destroys not only most of the bacteria present, but apparently also some of their poisonous products. When milk of average quality was fed, sterilized and raw, those infants that received milk, previously heated did, on the average, much better in warm weather than those that received it raw. No special varieties of bacteria were found in unheated milk that seemed to have any special importance with relation to the summer diarrhœas of children. The number of varieties is great and the kinds differed according to the locality from which the milk came. After the first twelve months of life, infants are less and less affected by the bacteria in milk derived from healthy cattle. When the milk has been kept cool, the bacteria did not appear to injure the children over three years of age at any season of the year unless present in great excess.

Of the methods of feeding now in vogue, it is believed that with milk from central distributing stations unquestionably possesses the most advantages, in that it secures some constant oversight of the child, and, as it furnishes the food in such a form that it leaves the mother least to do, it gives her the smallest opportunity of going wrong. The use for infants of milk delivered in sealed bottles should be encouraged whenever possible. Only the purest milk should be taken raw, especially in summer. To secure intelligent care, mothers and those looking after infants should be educated in the proper method of feeding. This, it is believed, can be most effectively done by the visits of properly qualified trained nurses or women physicians to the homes, supplemented by the use of printed direc-

tions. Bad surroundings, though contributing to bad results in feeding, are not considered the chief factor. The observations indicate that close percentage-modification of milk, although desirable in difficult cases, is not necessary for excellent results in the majority of infants, and that a certain adjustment of a healthy infant to its food is usually soon secured. Breast-feeding should be encouraged, as bottle-feeding is, as a rule, badly done. The injurious effects of table-food to infants under a year old and of fruits to all infants and young children in cities in hot weather should be much more generally appreciated.

LIMITATIONS OF BIOLOGICAL RESEARCH.

BIOLOGICAL research has but recently gained any considerable foothold in America. The practical importance of this field of observation commands our acknowledgment for the first time. There are doubtless many reasons why this is so. The fundamental cause, however, is to be found in our essential characteristic as a nation. We are above all a practical people. Scientific research without an immediate practical gain therefrom does not appeal to our inherent ideas. The lack of practical application and the apparent limitations of biological investigations have been our strongest arguments against the claims of this science upon our time. It is therefore not surprising that we have allowed others to lay the foundations in this department of knowledge. It is a fact, however, that the limitations of a science comprise no argument against its practical importance. European nations, especially Germany and France, have brought this clearly to view. Professor Loeb, in his address at the dedication of the Rudolph Spreckels Physiological Laboratory of the University of California, August 20, 1903, has particularly emphasized the practical importance of biological study. When we consider biological research, we should adopt the same standards which govern our decision concerning other departments of science; as, for example, physics and chemistry. One of the fundamental problems of biology is the production of living matter out of dead matter. This has hitherto been found impossible. The obstacles to be overcome seem unsurpassable. They constitute the great limitations of biological research. Such limitations are, however, neither different in kind nor degree from those encountered in physics and chemistry. Neither the production of perpetual motion, nor the making of gold, have been accomplished by the physicist or chemist. We nevertheless regard physics and chemistry as practical sciences. In these fields facts have been discovered which form the bulwarks of our modern civilization. After all, the biologist has evolved many facts which throw light upon the production of living from dead matter. We know that the substances found in living organisms have a definite chemical composition. They can be obtained outside the body. A living being maintains its existences by the constant transformation of dead into living matter. So far as the dynamics of this transformation are concerned, enzymes alone are operative. These enzymes do not differ in their origin from inorganic catalytic agencies. The anatomical structure of living beings is another important characteristic of their essential individuality. Upon such structure the action of the enzymes is vitally dependent. The transformation of one species of living beings into another species of living beings is a further biological problem. At present this seems as impossible of solution as the transformation of dead into living matter. Vital processes in living beings are chemical in character. The importance of physiological chemistry in the solution of biological problems is therefore apparent.

The force of Professor Loeb's remarks cannot be too highly appreciated. The solution of many practical problems lies within the domain of the biologist. Those already solved greatly increase our power over diseased conditions and our knowledge with respect thereto. Serum therapy owes its origin to biological study. Our accurate understanding of many of the infectious diseases is also to be ascribed thereto. The study of cytolysis, now being so extensively pursued, offers amazing therapeutic possibilities. As American clinicians, therefore, let us give our hearty support to research in this field, realizing that the object to be attained is the alleviation of the sufferings of mankind.

THEORY OF THE INCUBATION PERIOD OF ANTITOXIN RASHES.

AT times certain definite symptoms follow the inoculation of antisera. Such appearances comprise albuminuria, acute conditions of the joint and lymph glands and various cutaneous eruptions. Constitutional symptoms may also be present. The definite causation of these disturbances is not clear. Pirquet and Schick (*Wiener klinische Wochenschrift*, 1903, No. 45) have evolved a theory with respect thereto. They state that these manifestations are not due to the antibodies contained in the inoculated serum. This is shown by two facts, viz.: (1) The occurrence of the symptoms depends in no way upon the quantity or strength of the serum used. (2) The symptoms do not develop until seven or eleven days following primary inoculations. In secondary inoculations this period is from twenty-four hours to five days. The quantity of antibodies, however, is at a maximum immediately after the inoculation. As the result of serum inoculations certain reaction products are produced by the body. These products give rise to changes in the inoculated serum. When such changes reach a sufficient magnitude symptoms appear. The period of incubation is shortened following secondary inoculations because these reaction products are already present in the body as the result of the primary inoculation. Vaccination is a further example of this principle. The period of incubation is shorter following a re- than a primary vaccination. The reaction following the inoculation of tuberculin shows the same peculiarity. Here the clinical reaction produced demonstrates the presence in the system of reaction products against the tuberculous toxin.

We think it generally conceded that clinical symptoms are outward manifestations of the body toward pathological conditions. As the result of ordinary infections, and, as the authors suppose, antisera inoculations, such reactions are directed toward the products of the infecting microorganism or the inoculated material. By these reactions in both cases antibodies are produced in the system.

They are reaction products. Antibodies produced in the system as the result of ordinary or experimental infection occupy the same biological relation to the process as the supposed "reaction products" which arise as the result of inoculated antisera. That is, in both cases they combat the substances introduced. For all practical purposes, therefore, the views of the authors constitute a distinction without a difference. These various antibodies (reaction products) cannot as yet be accurately isolated. The supposition that they reach a maximum in the body *immediately* following the inoculation of antisera is warranted neither by laboratory nor clinical observations. Until more knowledge is obtained general theorizing with respect to "reaction products" is neither profitable nor wise.

The State and the Mosquito.

At last the mosquito question is regarded as of national importance, and men of light and learning in all branches of life have been brought to believe and to appreciate the fact that the mosquito is a foeman by no means to be despised. The mosquito has long been regarded as an excellent medium for jesting, and the evils which it brings in its wake have not been recognized at their full significance. Of course, up to a comparatively recent date, the disease-bearing properties of certain mosquitos were not known; but even now, the humorous side of the matter is more apt to crop up than is the grave. The convention called by Governor Murphy of New Jersey, and which held its session a short time ago in New York, discussed in all its bearings the situation as regards the mosquito. The meeting was attended not only by men of science, but by those prominent in various other ways. The suggestions advanced with a view of exterminating or of keeping out the insects were many, some of which seemed feasible, and some chimerical. Mr. Walter C. Kerr of Staten Island was of the opinion that if the City of New York would begin the work of extermination by spending $2000, the rural communities would continue it until mosquitos ceased to exist. Dr. L. O. Howard sent an interesting letter, and many others spoke or wrote. Finally resolutions were adopted recommending that a provisional committee be appointed by the convention to consider the formation of a central organization of national character, with which local bodies might coöperate in conducting a gigantic mosquito crusade.

The most gratifying and encouraging feature of the convention is that it signifies the awakening of the American people to the truth, that the mosquito has wrought and is capable of wreaking, an immense amount of injury to life and property. These insects have done incalculable harm in all parts of the world. Several of the European nations, and Japan in the Far East, have already organized vigorous crusades against the mosquito. This country has been slow in acting, but as soon as it is thoroughly well understood how great is the power for harm possessed by the mosquito, the United States will take measures which will equal or surpass those of other lands in suppressing the pest.

Tenement-House Inspection.

The New York *Evening Post*, December 19, has an article on some hitherto unpublished extracts from the report of the Tenement House Department. The inspection of tenements has been conducted during the past two years by 150 women, and most excellent results have been secured. Nearly all the inspections as yet made have been carried out in response to citizens' complaints, and from August 21, 1902, to June 28, 1903, 32,825 of these have been investigated. Out of this number, 17 per cent., or about 5000, were found to be without basis. In many instances, however, the sanitary conditions revealed by these inspections were frightful beyond compare. According to the report described in the *Evening Post*, "Pigs are still found in tenement cellars in Manhattan. Goats are even more frequent. Even a family cow is maintained in the nether depths by the more prosperous. Basements are constantly used as stables. In the living quarters all kinds of household pets are maintained, from mangy dogs and cats to white mice, parrots, and turtles. A favorite resort for pigeons is the wooden partition under the sink. Many tenements are overrun with chickens. Perhaps as bad are the "raw materials," especially rags in all stages of filth, which are stored in living rooms. One tenant who dealt in the entrails of animals made a practice of keeping his stock in his apartments. Rooms used for such purposes, too, are usually unventilated, and hardly need added stenches of this kind to make them uninhabitable."

There is an immense field of work in the tenement district of New York City, and the Department to which is relegated the duty of improving existing conditions, and of rendering the districts where dwell the poor, fit for human habitation, has a task which will tax to the utmost the energies of its members. The work has, so to speak, only just begun, but the results already attained augur well for a successful issue.

Fighting the Plague in Japan.

The manner in which the Japanese fight the plague and the plucky and unconcerned way in which those suffering from the disease endure their lot, is well described in the New York *Sun*, of December 22. The enclosed and segregated area where the stricken are detained, is about two hundred paces broad, containing some four or five hundred houses, surrounded by a corrugated zinc fence six feet in height. The fence is broken at intervals by a sort of lich-gate, guarded by two police officers. Along one side, barracks of corrugated iron had been erected within the barrier to accommodate the salved goods and chattels, and to shelter the owners thereof.

The most remarkable feature, however, of the isolation camp was the behavior of the inmates themselves. Despairing, dull, resourceless, and sullen countenances were absent, and in their place were exhibited smiling faces as if rather an amusing inconvenience than otherwise were being undergone. The particular methods of sanitation put into force did not seem to be altogether in line with those used in India and in other parts of the globe where plague flourishes and where European countries and America have control of the arrangements. In fact, the *Sun* correspondent was not quite clear as to what the scheme of sanitation might be. The point which most impressed the writer was the insouciance and absolute unconcern with which the Japanese faced the situation, just as they did when they fought China. It may be said that it is only about four or five years since the plague first appeared in the congested areas of Japanese cities and towns.

Reading in Bed.

The British public recently appear to have been greatly exercised in mind as to the effect upon health of reading in bed. The *Daily Mail* "set the ball rolling" by initiating a discussion among its

readers in regard to this matter. Many physicians who contributed to the symposium pointed out that the habit was a dangerous one, both on account of fire and the probabilty of injury to the eyesight. In an editorial in the supplement to the *New York Times*, attention is drawn to the fact that in these days there is no need to fear fire when reading in bed, as the use of a movable electric light will obviate all dread of this catastrophe. Persons, too, when they read in bed do not as a rule assume a recumbent position, and consequently their eyes should not be strained to any great extent. Many authors, it is said, protested against their books being utilized as sleep-producers, although the deadly narcotizing influence of the majority of the works of fiction produced nowadays cannot but be apparent to all who have the courage to dive into them. Reading in bed, however, is not to be recommended as a particularly healthful habit. Perhaps with some persons it is not injurious, while it may even be beneficial to a few.

The young should be prohibited from indulging in the practice, for putting on one side the probable strain to the eyesight, there is always the fear that the habit when formed will be abused, and that the hours which should be passed in recuperating the forces of the mind and body, will be spent in wasting these powers. It is never wise to burn the candle at both ends. In certain cases reading in bed is harmless, in some instances it tends to do good, but on the whole the practice is not one to be advised.

The Emoluments of the Ship Doctor.

The *Lancet*, December 5, contains a letter treating of this subject. A correspondent of a recent edition of *Lloyd's Weekly* has expressed the views of a ship doctor in the following words: "Many travelers are in doubt as to the position of the ship's doctor in regard to his remuneration from passengers for services rendered. The Merchant Shipping Act enacts that every foreign-going vessel having 100 persons on board or upward, shall carry on board as part of her complement a duly qualified medical practitioner. Furthermore, an emigrant ship—*i.e.* a foreign-going vessel which carries 50 or more steerage passengers—must have a medical man irrespective of the number of crew or of the other passengers carried. The salary of the doctor on board is commensurate with these duties to his ship. To any passengers who are suffering from ordinary forms of sea-sickness and its concomitant evils or who receive injuries which are in any way due to the ship, the doctor's services are free. For any sickness contracted before sailing or during a voyage which is not connected with the above-named conditions he is entitled to a remuneration at the same rate as he would receive on shore. Obviously it would be as unfair to expect that his services to passengers should be rendered *gratis*, as it would be for any visitor in a hotel or traveler on the railway to expect to have medical attendance free in any illness for which the hotel or railway authorities could not be held responsible."

The writer to the *Lancet* says that the case of the ship's surgeon is stated with accuracy in the above sentences, and adds that ship's surgeons are of two kinds: (1) those who after they have qualified take such a position either for health or for pleasure, and (2) those who elect to make sea life a permanency.

The pay of the ship's doctor varies from $30 to $5c per month. This is for duties to officers and crew As regards passengers in relation to the surgeon, the following groups will include all: (1) The passenger who takes the initiative by remunerating the surgeon, perhaps handsomely, for any services rendered; (2) the passenger who asks for his bill and pays it if reasonable; (3) the passenger who traveling for the first time does not know whether to ask for his bill or to wait for it to be delivered, but is pleased to be enlightened on the matter; (4) the passenger who clings to the old-time notion that the surgeon is there solely for the benefit of passengers, and (5) the passenger who never intends to pay the surgeon.

Americans, perhaps, are the greatest travelers in search of change and amusement in the world. Consequently the question of the ship's surgeon's fees should be particularly interesting on this side of the water. It is distinctly obvious that if the ship's doctor had to depend solely on his emoluments as such, his lot would be but a sorry one. A condition of affairs of this character would recoil on the heads of the passengers, for no able man would be found to fill the position. It is therefore manifestly right and just that the ship's doctor should be paid for his services to passengers on board ship in the same manner and at similar rates of remuneration as he would expect to receive on shore. The question of collecting the bills is another difficult one. It has been suggested that the bill should not be sent in the surgeon's name, but in the company's name. One thing, however, is plain, that the ship's doctor should be paid by the passengers, and those who either ignorantly or wilfully evade so doing should be informed of the true facts of the case.

The Foreigners Who Become Citizens and the Desirable Immigrant.

The *New York Times* of December 18 has an interesting annotation on the above subject. It is a matter of widespread belief that the British as a rule are very averse to becoming citizens of any country. Members of this race are scattered throughout the globe, and it is laid to their charge, that while willing enough to "spoil the Egyptians" they are by no means desirous of relinquishing their rights and privileges as British citizens. This characteristic of the Anglo-Saxon race from the other side of the water, and which is thought to be largely evidenced in its members who live in the United States, has frequently given rise to heart-burnings and gentle recriminations on the part of the inhabitants of this country. However, figures compiled by the Massachusetts Bureau of Labor Statistics would seem to belie the truth of the statement that Englishmen but seldom take out their naturalization papers in the United States. At least such is not the case so far as the State of Massachusetts is concerned, and probably is not so throughout the country. In regard to other foreigners who become naturalized in the aforementioned New England State, the Irish stand first in the table of eligible and naturalized percentages, 79 out of every 100 with the necessary qualifications, for swearing the land of their birth for the land of their adoption. The Germans take second place, with 74 out of 100, while the maligned British are third with 67 out of 100. Then come Swedes with 53, Canadian French with 46, Russians with 44, Poles with 41, and lastly, quite at the end of the line, come the Italians with 37 out of every 100. Much has been said and written of late in regard to the desirable and undesirable immigrant. The ideal desirable immigrant is the healthy individual able to read and write English, knowing a trade, having some money and intending to become a citizen. Next in importance comes the healthy individual unable to read or write English, knowing a trade, having some money and intending to become a citizen. Next in order comes the healthy individual whose only stock in trade is his health and strength and a little money,

and intending to become a citizen. At one time such persons as these flocked into this country in large numbers, but now all has changed in this respect. A large portion of the immigrants who crowd into the United States in vast numbers at the present time are, from most points of view, eminently undesirable. Ignorant, dirty, and unhealthy, they mass into the cities and towns, accentuating the already insanitary conditions existing there. Furthermore, with all the precautions taken, they ofttimes introduce and spread diseases of many kinds. It is a question whether the limitations placed upon the admittance into the country of such as these are sufficiently stringent.

News of the Week.

The Unauthorized Use of a Name.—In the current issue of one of the monthly magazines appears a paper on the so-called "nature cure" to which is appended a note by one of the editorial staff of the MEDICAL RECORD. The note was written at the request of the editor of the magazine for an editorial comment on the subject of the paper, and it was given under the implied understanding that, as an editorial note, it was anonymous. The addition of the signature, incorrectly written, and of the title, incorrectly stated, was made without the writer's knowledge or consent.

Examination for Physician in the Philippine Service.—The United States Civil Service Commission announces that on January 27–28, 1904, an examination will be held at various places in the country, to secure eligibles from which to make certification to fill vacancies in the position of physician in the Philippine Service, at salaries ranging from $1,200 to $1,800 per annum, and other similar vacancies as they may occur in that service. The examination will consist of the following subjects, which will be weighted as indicated: letter-writing (5), anatomy and physiology (10), chemistry and materia medica (10), surgery and surgical pathology (20), practice and special pathology (20), bacteriology and hygiene (15), obstetrics and gynecology (10), experience (rated on application) (10). Questions on practice will be principally upon tropical diseases. The principles of bacteriology and hygiene as applied to the study of and prophylaxis in diseases incident to the tropics will be especially considered. At least one year's experience in hospital work, or in the Philippine Islands as assistant surgeon in the United States Army, is prerequisite. Each applicant will be required to submit to the examiner, on the day he is examined, a recent photograph, not more than three years old, of himself, which will be filed with his examination papers, as a means of identification in case he receives appointment. An unmounted photograph is preferred. The date, place, and kind of examination, the examination number, and the year in which the photograph was taken should be indicated on the photograph. The age limit is twenty to forty years. This examination is open to all citizens of the United States who comply with the requirements. Appointees are expected to pay their traveling expenses from their places of residence to Manila, but if it is found necessary for the Philippine Government to bear any part of such traveling expenses 10 per cent. of the monthly salary of the employee will be retained until the amount retained is equal to the amount borne by the Government. At the expiration of two years' satisfactory service the actual and necessary traveling expenses borne by an employee in proceeding to Manila will be refunded to him. He will be allowed half salary from the date of embarkation and full salary from the date of his arrival in the islands, provided that he proceeds directly to the islands; otherwise, he will be allowed half salary for such time only as is ordinarily required to perform the journey by the route directed. The half salary allowed him from the date of embarkation until his arrival in the islands will not be paid until after two years of satisfactory service. Each employee will be required to sign an agreement to serve at least two years in the Philippines unless sooner released by the civil governor or proper head of Department. A person who has been employed continuously in the Philippine Service for three years or more is, upon his request when retiring from that service, furnished transportation from Manila to San Francisco, and is allowed half salary for thirty days in addition to full salary for the period which he may be granted as leave of absence. Competitors will be rated without regard to any consideration other than the qualifications shown in their examination papers. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application Forms 2 and 375, which should be properly executed and filed with the Commission at Washington. Persons who are unable to file their formal applications and who notify the Commission of this fact, either by letter or telegram, with the request that they be permitted to take the examination, will be examined, provided their requests are received at the Commission in sufficient time to ship examination papers.

The Pathological Society of Philadelphia.—The Annual Exhibition Meeting of the Philadelphia Pathological Society will be held on Thursday evening, January 14, 1904, at 8 P.M., at the Mutter Museum of the College of Physicians. This exhibition includes extensive gross and microscopic exhibits embracing every department of human and animal pathology. Members of the medical profession are invited to attend.

A Museum of Security.—The Institute of Social Science purposes to establish a museum in which shall be exhibited all inventions designed as safeguards against accidents. There are several such museums in Europe, the influence of which has tended to diminish markedly the number of accidents of various kinds in the countries where they are located. The proposed museum is to contain working models of safety devices for use on railways, in mines, on sailing vessels and steamships, in city streets, in elevators, in factories, in buildings in course of construction, etc.

Increase in Pneumonia.—According to the figures of the Department of Health pneumonia patients in this city to an unprecedented extent. The number of deaths has steadily increased from week to week since the second week in November, when 154 deaths were recorded. The next week 208 deaths occurred, and during the subsequent seven days there were 231 deaths from pneumonia. The succeeding weeks show 241, 245, 261, and 269 deaths. The Board of Health is, it is said, considering the advisability of a change in the sanitary code, placing pneumonia among the infectious and therefore notifiable diseases.

Tuberculosis in the Fire and Police Departments.—It is said that the Board of Health has decided that no policeman or fireman suffering from tuberculosis shall be retained for active duty. Since the disease is infectious, it is asserted that it would endanger the general health of the city to allow officers suffering from tuberculosis to room with well men, as is necessary in the dormitories while on reserve duty.

A few men will be affected by the order, and will be retired. Those in whom the disease is not far advanced will be assigned to work that will permit them to sleep at home. Seventeen policemen have been reported as suffering with tuberculosis.

Three Generations of Physicians in One Appointment.—Dr. Arthur J. O'Leary, Register of the Bureau of Vital Statistics of the Borough of the Bronx, has been appointed visiting physician to Manhattan College, to succeed his father, Dr. C. N. O'Leary, who was killed in a railroad accident recently. Dr. A. J. O'Leary's grandfather was appointed to the position at the organization of the college, and was succeeded by his son, Dr. C. N. O'Leary.

Discovery of the Smallpox Germ.—The newspapers of recent date published depatches from Cleveland announcing that Dr. W. T. Howard, Jr., of that city had discovered the germ of smallpox, and that the particulars of his find would be made known very soon. In reply to an inquiry regarding this, Dr. Howard writes that he has never stated directly or indirectly that he had discovered a microorganism which was the cause of smallpox, nor has he authorized anyone to make such a statement. He writes: "In the discussion of Councilman's paper at the meeting of the American Association of Pathologists and Bacteriologists in May last, I stated that, through Dr. Councilman's courtesy in giving me his methods, I had been able to *confirm* many of the statements he made in regard to the bodies he described in smallpox, and that I agreed with him that these bodies are parasites and the cause of the disease. I am still of the opinion—indeed, I am more convinced than before—that these bodies described and discovered by Councilman and his pupils are parasitic in nature and the cause of the disease. But I disclaim and repudiate entirely the recent newspaper statements that I have discovered the cause of smallpox."

Typhoid Fever Spreading from Butler.—The epidemic of typhoid fever at Butler, Pa., has nearly burned itself out for lack of fresh fuel, but the poison elaborated there is now working destruction at other places. In Pittsburg the disease is increasing rapidly and has already assumed the proportions of an epidemic. During the first twenty-three days of December there were 499 cases reported to the health authorities, the daily average increasing progressively until on December 23, there were 49 new cases. The drainage of Butler itself reaches the Ohio River at some distance below Pittsburg, but the Allegheny River above the city drains much of the country adjoining Butler, and it is probably through infection of this stream that the outbreak in Pittsburg has occurred.

Dr. Maximilian Herzog, who for more than seven years has been professor of pathology and bacteriology in the Chicago Polyclinic, has been appointed pathologist in the bureau of government laboratories at Manila.

An Incident of Medical Practice.—A correspondent of the *New York Times* in Duluth relates a recent experience of Dr. William Goldsworthy of Two-Harbors, which was exceptionally trying even for country practice in the cold north. An employee of the Duluth and Iron Range Road fell seriously sick while looking at some land forty miles in the interior of Lake County. He was accompanied by two other men, one of whom went thirteen miles to a telephone in a logging camp, and called up Dr. Goldsworthy at Two-Harbors. The doctor said he would go. It was necessary for him to drive twenty-two miles over a rough road, and the other eighteen miles must be covered on snow-shoes. He drove all night to have daylight for the snowshoe trip. The patient was in a deserted logging camp and very low. The doctor and the other men made a stretcher of boughs and carried the patient over the eighteen miles to the team, and he was then taken to the hospital at Two Harbors.

The Eastern Medical Society of New York has engaged permanent quarters at Clinton Hall, 151-153 Clinton street, New York. Possession will be taken on or about January 1. The building will offer every facility of the modern clubhouse, all of which will be open to the members. A reference library is one of the projected features of the society. At the annual election, held recently, the following officers were elected: *President*, Dr. Louis J. Ladinski; *Vice-Presidents*, Drs. David Robinsohn and Tobias Berger; *Treasurer*, Dr. Joseph Barsky; *Corresponding Secretary*, Dr. Abr. L. Wolbarst; *Recording Secretary*, Dr. A. J. Ronginsky. Dr. Wolf Freudenthal was elected trustee for three years. The chairmen of the new committees are: Committee on Ethics, Dr. A. A. Himowich; Committee on House, Dr. E. K. Browd; Committee on Admission, Dr. John A. Price; Committee on Library, Dr. Charles Rayevsky.

Philadelphia Neurological Society.—At a stated meeting, held December 22, Dr. Jas. Hendrie Lloyd exhibited a patient with paralysis of the ulnar nerve following a severe attack of typhoid fever. After pointing out the rarity of isolated paralysis of the ulnar nerve he related the case of a man, in whom symptoms of such a condition developed in the sequence of an attack of typhoid fever, treated with cold baths and other measures. Owing to the unlikelihood of any constitutional disturbance, infective or toxic or febrile, or even the bathing, causing the disorder, it was believed that in view of its local character it was possibly due to traumatism accidentally inflicted in the course of the necessary therapeutic manipulations. Dr. John H. W. Rhein exhibited a case of syringomyelia, occurring in a woman fifty-five years old in whom the first symptom noted had been impairment of vision, with the presence of leucin-bodies in the eye. Later, symptoms of spastic paralysis made their appearance, and apoplectiform attacks, followed by hemiplegia, and the development of characteristic impairment of thermal and tactile sensibility. Dr. Joseph Sailer read a paper entitled "Tetany as a Complication of Gastric Disease," reporting a case occurring in a woman with symptoms suggestive of pyloric obstruction and gastrectasia, the acidity of the gastric juice being notably increased during the attack. Dr. Wm. R. Dunton read by invitation a paper entitled "The Pathology of Dementia Præcox." Drs. Wm. G. Spiller and C. D. Camp presented a communication entitled "Two cases of Multiple Sclerosis, with Necropsy."

Stony Wolde Sanatorium.—The Board of Directors of this sanatorium announces that the institution is now open for the reception of patients. A resident physician, Dr. H. L. Barnes, is in charge. There are at the present time between twenty and twenty-five patients, the present capacity of the sanatorium being sixty. A fixed charge is made of seven dollars per week, which covers all expense to the patient excepting that of laundry, which is twenty-five cents per week extra. It is requested that applicants who are passed be referred to the president, who will give them all necessary detailed information. It is also requested that the Medical Board should bear in mind the fact that the institution is for incipient cases of tuberculosis occurring among women and children. No boys

over twelve years of age are admitted. Any further information may be obtained by addressing the president of the sanatorium, Mrs. James E. Newcomb, 118 West Sixty-ninth street, New York.

Antitoxin in Diphtheria.—The Chicago Health Department, in its latest Bulletin, makes the following comment on the value of antitoxin in cases of diphtheria: "Since the introduction of antitoxin in the treatment and prevention of diphtheria its mortality rate has been reduced by nearly one-half —that is, from an annual average of 6.25 deaths in every 10,000 of the population in the seven years 1889-1895 to an annual average of 3.24 in the seven years 1896-1902 of antitoxin treatment. But this is not enough. The seven years' experience clearly proves that no child should—that no child ever did—die of diphtheria when treated early enough with a sufficient quantity of good antitoxin. The pre-antitoxin mortality of diphtheria in Chicago was about thirty-five deaths in every one hundred cases of the disease. In the many thousands of cases among the poor and destitute treated by the Department inspectors under the most adverse conditions the rate for the whole number has been less than seven deaths in the one hundred cases. And there are many physicians in Chicago and elsewhere who have records of hundreds of cases with a rate of less than two deaths per hundred.

The Tuberculosis Congress Muddle.—Some weeks ago the officers of one of the so-called American congresses on tuberculosis officially requested the President of the Indiana State Medical Association to appoint delegates to the Congress which it is reported will convene in St. Louis early in 1904. The matter was referred to the Council of the Association, which, after deliberation, passed a resolution to the effect that "The Council of the Indiana State Medical Association, representing the medical profession of Indiana, believing that the so-called American Congress on Tuberculosis, organized by Clark Bell, Esq., of New York, is not a body which is representative of the medical profession or of the best scientific thought of this country, deems it inadvisable and inexpedient for the Indiana State Medical Association to be represented in said Congress."

"Weltmerism" has received another set-back by a recent decision of the United States Supreme Court. Weltmer and a number of assistants advertised extensively in the lay press claiming to work many cures by "magnetic healing." Their offices were in Nevada, Mo., and their business grew to such proportions that the postmaster in Nevada was compelled to hire additional help to handle the mail. After an investigation by the Post-office Department, the business was declared fraudulent and they were prohibited from using the mails. C. M. Bishop published an open attack on the methods of Weltmer, who sued Bishop for libel. The Supreme Court of Missouri refused to find the article libelous, on the ground that Weltmer had failed to show that the business was entitled to the protection of the law. The United States Supreme Court dismissed the case for want of jurisdiction, thus in effect affirming the decision of the Supreme Court of Missouri.

Dr. L. Pierce Clark has been appointed visiting neurologist to the New York Children's Hospitals and Schools, Randall's Island.

"La Gazzetta Medica" is the title of a new medical journal published in Italian in this city. It is to appear monthly under the editorship of Dr. Giuseppe Lapenta.

The International Congress of School Hygiene.—This congress, which will be held in Nuremberg, April 4–9, 1904, promises to be of considerable importance. The following are the titles of addresses to be delivered during the general sessions: (1) Professor Cohn of Breslau, "What Has Ophthalmology Done for School-hygiene and What Has It Still To Do?" (2) Prof. Axel Johannesen of Christiania, "On the State of School-hygiene in Norway." (3) Dr. Le Gendre of Paris, "On the Hygiene and the Personal Diseases of Teachers with Regard to Their Relations to the Pupils." (4) Dr. Sickinger of Mannheim, "Organization of Elementary Schools Based upon the Natural Capacity of the Children." (5) Professor Liebermann of Buda-Pesth, "On the Tasks and the Instruction of School Physicians." (6) Professor Hueppe of Prague, "Prophylaxis of Infectious Diseases in the School." (7) Professor Eulenburg of Berlin, "On Suicides of Scholars."

Unfavorable Report of Schmidt's Cancer Serum.—It is stated in the *British Medical Journal* that six cases of cancer are at present under treatment with Dr. Otto Schmidt's serum in the Middlesex Hospital. The treatment is being carried out by Dr. Jossé Johnson with the permission of the surgeons of the hospital. The cases were examined by Dr. Schmidt, who pronounced them to be suitable for the purpose. Although at the time the note was written they had been under treatment for more than a fortnight, no reaction had been set up and no appreciable effect of any kind had been produced on the growths.

Dr. Charles W. Dabny, President of the University of Tennessee, who has been asked to take the Presidency of the University of Cincinnati, was given a banquet by the Faculties of the Medical and Law Departments in Cincinnati. The dinner took place at the Phœnix Club on December 23. Among those present were Dr. P. S. Conner, dean of the faculty, and Drs. Reamy, Palmer, Forchheimer, Ransohoff, Hyndman, Rachford, Zinke, Ravogli, Ayres, Phelps, Bonifield, Whitacre, Crane, and Freiberg. Professor Dabny has not yet consented to accept the position, but will give his answer about the first of the new year.

Hospital for Children in Chicago.—A children's department has been established by the Provident Hospital in Chicago. The little patients will be cared for by the colored nurses, which that institution is training. In connection with this department a clinic has been instituted on Tuesdays and Fridays, from two to four P.M.

Additional Buildings for Dunning.—The County Board of Commissioners has decided to erect at Dunning, Ill., a cottage for working patients, and a new morgue and pathological laboratory. At the Cook County Hospital, Chicago, a children's building will be erected.

Medical Appointments in Chicago.—The Board of County Commissioners of Cook County has approved the appointment of Dr. Charles Whalen to the County Hospital. Dr. V. H. Podstata has been reappointed as superintendent of the Cook County Institutions, at Dunning, and Dr. Warren H. Hunter has been reappointed as County Physician.

Directory by the Chicago Medical Society.—It has been announced that this society will issue a directory of the medical men of Chicago, in which will be given office hours, telephone numbers, specialties, etc.

Preliminary Training for Students of Nursing.—At a meeting of hospital superintendents recently held at Mercy Hospital, Chicago, it became apparent to the hospital authorities that they are overrun with applications for positions as nurses by those without the necessary qualifications or training. In order that this condition of affairs may be corrected,

a board, which is to be appointed by the Illinois Association of Graduate Nurses, is to be given control of all applicants for three months, during which time they shall be trained in cooking and adaptability, and, if found satisfactory, shall then be given certificates admitting them to real hospital work.

Obituary Notes.—Dr. WM. H. WEBB died in Philadelphia on December 22 at the age of fifty-eight years. He was graduated from Jefferson Medical College in 1866 and from the Philadelphia College of Pharmacy in 1868. He served as surgeon in the United States Army during the Civil War.

Dr. DANIEL EMBURG KISSAM died at his home in Huntington Harbor, L. I., on December 23. Dr. Kissam from 1848 to 1888 practised his profession in Brooklyn. He was a native of New York City, and was born October 3, 1817. He was for many years visiting surgeon to the Brooklyn Hospital. During the Civil War he served as a surgeon in the Union Army.

Dr. CHARLES H. BUSHONG died at his home in this city on December 20, at the age of forty-seven years. He was born in Lancaster County, Pa., and was graduated from the College of Physicians and Surgeons in this city in the class of 1885.

Dr. HORACE CLIFTON TAYLOR, ninety years old, died at Brocton, N. Y., on December 21. He was a graduate of the Eclectic Medical Institute, Cincinnati, in 1849. He was well known as an author of works on the care of the indigent. He served eleven years as County Superintendent of the Poor.

Dr. HUGH M. WALLIS of Houma, Terrebonne Parish, died at Covington, La., on December 26. He was sixty-nine years old, and a native of Kent County, Maryland, but a resident of Terrebonne Parish, Louisiana, for forty-one years. He was a graduate of the Jefferson Medical College, Philadelphia, in the class of 1860. He was Mayor of Houma for several terms, Coroner of Terrebonne Parish, and owner and editor of the Houma *Times*.

Obituary.

AIMÉE RAYMOND SCHROEDER, M.D.,

NEW YORK.

DR. AIMÉE RAYMOND SCHROEDER, who died in this city on Christmas Day after a brief illness, was the youngest daughter of the late Henry J. Raymond, founder and editor until his death of the *New York Times*. She was born in 1857, and much of her early life was passed in Europe where, in France and Italy, she received the education upon which were based her rare literary and artistic accomplishments. She was graduated from the Woman's Medical College of the New York Infirmary in 1889, and at once entered upon the duties of her profession, but retired from active practice upon her marriage to Dr. Henry Harmon Schroeder in 1893. She always, however, remained an earnest student of medicine, and was for many years, up to the time of her death, a faithful and most valued member of the editorial staff of the MEDICAL RECORD.

Aimée Schroeder was a woman of unusual mental attainments, an accomplished linguist, a pianiste, and a writer of pure English—but it was by her exceptional qualities of heart that she bound to herself the wide circle of devoted friends whose privilege and joy it was to know her and to whom her memory will always be an uplift and a precious possession. She was most happily named, for never was there woman more beloved by all who were brought within the influence of her gentle presence than was this bright spirit.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BRADSHAW LECTURE ON CANCER—TROPICAL SCHOOL—SLEEPING-SICKNESS—TYPHOID IN WATERCRESS—SMALL-POX—DUBLIN HOSPITALS—SIR B. MAPLE'S WILL—BART'S—THE LATE SURGEON-GENERAL SYLVESTER.

LONDON, December 11, 1903.

THE Bradshaw lecture at the Royal College of Surgeons was delivered on Wednesday afternoon by Mr. Henry Morris. The president took the chair and there was a good attendance of Fellows and members. The president of the Royal College of Physicians (Sir W. Church) was also present, which seems natural, as the lecture was on cancer and its origin, and the two colleges are now jointly engaged in the research on this subject.

Mr. Morris reviewed some of the theories that have been put forward in the last thirty years and dismissed them as unsatisfactory, inasmuch as they have not been shown to have a causal relation to cancerous disease. In fact, our knowledge at the present day is so little that the researches undertaken by the two colleges, though promising much for the future, start from a basis of past observation. To speak of cancer as an infectious or contagious disease was calculated to raise needless alarm in the public mind. Cancer was not parasitic in the sense of being caused by a microbe. Nor was it contagious in the sense of being transmissible from one person to another through the ordinary channels. But it was parasitic and infectious in the way in which it spread in, and lived independently of, the tissues which it involved. Moreover, it was contagious in the sense of being autoinoculable. No doubt the carious tooth and the clay-pipe might play a pernicious part by exciting tumor formations into activity, but they could not *per se* be the causes of malignant disease. In the lecturer's view we must look to a tumor germ for the explanation of the causes of growths, both benign and malignant, congenital and postnatal, for there was no lack of evidence that tumors arose from matrices of postnatal origin. The germ theory had been proved to account for a variety of benign tumors, and he believed it would be found to be the true explanation of malignant disease. Up to the present time the microbic theory had not advanced our knowledge of cancer one iota, in spite of the great talent and skill devoted to it, whereas year after year evidence had been forthcoming in support of the germ theory—some of it even without being sought for. This theory was convincing as to the local origin of cancer and as to its curability—if the growth was removed early and completely. But of course that offered no guarantee against the development of a new malignant growth at a future time any more than the union of a fractured bone afforded a guarantee against another accident of the kind. Mr. Morris advocated the earlier and more frequent removal of even non-malignant tumors. He cherished the expectation that the exhaustive researches undertaken by the two colleges would yield valuable results.

The London School of Tropical Medicine—"What It Has Done, Is Doing, and Hopes to Do," was the subject of an address by Sir Patrick Manson on Monday. He began with a warm tribute to the late Colonial Secretary, whom he described as the mainspring in the movement for education in tropical medicine, without whom the world would have been poorer to-day in respect to many important facts which the schools he called into existence have accumulated; in this matter, he said, Mr. Chamberlain deserves a more honorable title than imperialist—he was a humanitarian. As to the results already achieved by the men connected with the school, Sir P. Manson mentioned that it was the present superintendent, Dr. Low, whose observations showed how filaria gained access to the body—thus indicated the way in which it must be avoided. Again Dr. Sambon and Dr. Low sent by the school demonstrated by experiments which might very well have proved serious to themselves that man could live in the midst of malaria, if he would but employ simple and practical measures against mosquito bites. The school imported infected mosquitos from the Roman Campagna and with them infected healthy persons, thus giving the final proof that malaria was conveyed by mosquitos. Dr. Forde was another alumnus of the school, and he discovered in the blood of a man a new parasite, afterward recognized by Dr. Dutton of the Liverpool school as the cause of grave disease in the lower animals. Only last year another alumnus, Dr. Castellani, demonstrated the association of this parasite—a trypanosoma—with sleeping-sickness. Subsequent research by Colonel Bruce and others had corroborated Dr. Castellani's discovery. Until a

fortnight ago it could not be declared as absolutely certain that this trypanosoma was the cause of sleeping-sickness. The presumption was very strong, but there was a possibility that its presence in the disease might be only a frequent concurrent circumstance. That possibility may now be considered disposed of, for last year a woman was admitted to their hospital who was suspected to have trypanosomes in the blood. Dr. Daniels, by long research, showed the conjecture to be well founded, for he succeeded in detecting the parasite in the patient's blood. Efforts at treatment proved futile, and the patient left last March, but specimens of her blood were sent to the laboratory from time to time. Two months ago she began to show symptoms of sleeping-sickness and died of the disease on the 26th ult., two years and three months after being bitten by the tsetse fly on the Upper Congo, where she lived.

Sir Patrick closed his address with an appeal for money. They wanted, he said, £100,000, or as much of that sum as they could get. They had given full value for more—for ten times more. Apart from education, anyone of the discoveries he had mentioned was worth more—more, indeed, than they would ever receive. So he had no hesitation in asking for something more on account.

Sir W. Church proposed and Sir F. Young seconded a vote of thanks for the address and congratulation on what the school had already done—a vote which was heartily carried.

The London County Council has generally been alive to sanitary matters. This week the danger of typhoid being spread by watercress was brought forward, and it was proposed to seek powers to control all the beds where it is grown within the county. Yesterday the same matter was brought before the City Corporation and referred to its sanitary committee. The present excitement which gives point to these proceedings arose in a report of Dr. Warry, M.O.H. for Hackney, to the health committee of that borough. In an outbreak of typhoid fever, Dr. Warry found a large percentage of the patients had eaten watercress, and he could not trace the epidemic to other sources, such as milk, shell-fish, etc. He, therefore, took samples of the cress from the suspected places and found sewage organisms. The water from the beds was also found to abound in bacilli coli. It is expected that means will now be adopted to prevent the growth of the salad in sewage-polluted streams.

There is an outbreak of smallpox at North Shields which has rapidly increased for the last few days. Six cases in the last two days were reported, three in one house and one near the isolation hospital. There have also been two in one street in the adjacent village of Preston. The patients have been removed to the hospital three miles from the town, where twenty are under treatment. The Tynemouth guardians, under pressure from the Local Government Board, have agreed to placard the district, recommending vaccination and revaccination.

The Nobel Prize for Medicine has been awarded to Professor Finsen. I hear he was too ill to attend the public distribution of the prizes yesterday at Stockholm. At the meeting of the Phototherapeutic Institute a Copenhagen dispatch says it was announced that the professor would give 50,000 kroner to the institute and two other governors would each give the same amount.

Lord Iveagh's gift to the Dublin hospitals has been apportioned. The donation, £50,000, is not to be used to add to the number of beds. No other condition is attached.

Sir Blundell Maple's will not only provides for the completion of University College Hospital, but directs £3,000 a year for several years to be subscribed to charities.

The opposition to the scheme proposed for North Bartholomew's is growing, and the press is evidently passing round to the advocacy of a larger one.

Surgeon-General J. H. Sylvester, I.M.S., died on the 29th ult., aged seventy-four years. He saw much service in India from 1854 to 1875. Part of the time he was professor in the Grant College and physician to the Jamsetjee Jeejeebhoy Hospital. After his retirement he devoted much time to painting.

Brain-weight of Japanese.—The brain of the Japanese grows more slowly during infancy and early youth than it does in the European. In the adult the brain-weight compares favorably with that of Europeans of similar stature, and it may be shown to be superior in this respect to other races of the same general stature. These facts are of not a little significance in relation to the learning, industry, and aptitudes of this progressive race.—E. A. Spitzka in *Science*.

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CURIOUS BELIEFS AND CUSTOMS OF THE PHILIPPINE-ISLANDERS AFFECTING THE PRACTICE OF MEDICINE.

Manila, November 9, 1903.

In the mountains of central Luzon live several hundred thousand Igorrotes, wild tribes of head hunting-savages, who have successfully withstood all efforts of the Spanish priests for their conversion and civilization. The Spaniards interfered with them but little, and although the Americans have stopped the head-hunting expeditions, the Igorrotes still live in primitive savagery. Of late, the Episcopal church has opened a mission among them, and the insular government has sent several physicians to them as provincial health officers. Medical practice among them is, however, attended with great difficulties, due to their superstitions and religious beliefs. To the Igorrotes, the world is peopled with the unseen ghosts of the departed, called "Anitos," who have the power for good or evil, and usually prefer to exercise the latter. All diseases, injuries, and deaths are believed to be directly caused by anitos. If smallpox kills half a dozen persons in a village, the fell work is that of a malignant anito; if a man receives a stone bruise on the trail, an anito has entered into the foot and must be removed before recovery is possible. If a person slips or falls, an anito pushed him. When several years ago two Bontoc Igorrote men died of poison administered by men of another town, the verdict was that the administering hands were directed by a diabolical anito. One knows that in walking in the forest one is surrounded with anitos, ever anxious to push one over a cliff or visit disease upon one. For this reason it is necessary to carry a special kind of barbed spear, of which alone the anitos are afraid. The anitos, who are the departed spirits of a certain family or tribe, are supposed to protect their descendants, and thus in time of epidemic disease the first duty of the Igorrote is to hold a feast to propitiate his ancestral anitos and secure their protection. To this feast come all the clan, and thus any existing infection is given every opportunity to spread widely among them. Obviously, preventive medicine and hygiene cannot be understood and appreciated while such beliefs are entertained.

Since the "anito" is the cause of all bodily affliction, the function of the person who battles for the health of the afflicted is that of an anito exorcist. Many old men and women, known as "insupok," are credited with considerable success in urging the offending anitos to leave the sick. The formula is simple: the "insupok" place themselves near the affected part, usually with the hand stroking or touching it, and say, "Anito, who makes this person sick, go away." This they repeat over and over again, muttering to themselves, and frequently exhaling the breath to assist in the departure of the anito, just as one blows away the dust. Occasionally the injured part is moistened with saliva. As compared with the "physician" of other primitive people, the "insupok" is a beneficial force to the sick. The methods are all quiet and gentle. There is none of the rattle-shaking, drum-beating, and medicine-dancing seen among the Indians of the United States, or the pounding of tom-toms or clashing of metal found among Asiatics or Africans. Under the "insupok" treatment the body is not exhausted, nor is the mind distracted, or the nerves racked. In a positive way the sufferer's mind is often relieved, and in many cases physical relief results from the stroking and rubbing. The fee of an "insupok" is fixed by custom at an allowance of rice equal to two-fifths of a laborer's daily wage. "Insupok" are not appointed by the people, but are informed in a dream that they are to be "insupok" and have influence over the anitos. Besides the "insupok" any member of a household has power to act as mediator between a sick relative and the offending anito, or the soul of the sick about to depart. There are several household ceremonies based upon this idea. If one is taken sick or is injured, the person acting as mediator goes from the house to the mountains or a river, having a live chicken in a basket, a little basi, or native fermented drink, and some rice. On arriving at the proper place, this person points a stick in various directions, saying, "Come, soul of——, come with us to the house to feast." If this is not done, the soul of the sick person may be enticed from the body by an anito and will not return. Usually a woman performs this ceremony. After the latter has been properly performed, the mediator returns to the dwelling, kills and cooks the chicken, and with other members of the family, eats it. If the gall of the chicken is found to be dark colored, the prognosis in regard to the sick person is favorable, but if it is light colored one is wise to expect only the worst.

After death has occurred the body of the deceased is kept for days in the house, sometimes for as long as a month. The body is laid on a frame and braziers of glow-

ing charcoal kept beneath it. The heat is constantly maintained, and the fire frequently fed with the dried flesh of cattle belonging to the deceased. This procedure is kept up until all the herd of cattle is exhausted, all being slaughtered and disposed of in this way and none being left for the heirs. The fumes of the meat pass into the body of the departed and nourish its spirit in the hereafter, making it kindly disposed toward those who have thus provided it with food and inclined to protect them against the machinations of the evilly-disposed anitos.

Among the Mohammedan Moros, the practice of medicine and healing of the sick lies with the priests or "hadjis." A few simple remedies are used, but prayer to Allah is the only really efficacious measure. However, if Allah has made up his mind in the matter, prayers are useless, and thus are only valuable when the deity is as yet undecided. When Allah decides that the time has come for a man to die, nothing can save him, but on the other hand, it is unnecessary to take any special hygienic precautions, because until their alloted days have come to an end Allah preserves all true believers. Clearly the sanitary ideas of the pig-eating Americans are of no avail in staying the hand of the Omnipotent, and being both useless and troublesome, there is no use in observing them. Man has no hand in the preservation of life, but Allah settles all things. A fatal case of cholera was foreordained—Allah had long ago decided when and how the man should die, and has now decided when and how his relatives and friends will depart. It is futile, therefore, to disinfect or quarantine.

"Running amuck," as practised by the Moros, is the result of religious erotism. Every true believer is provided by Allah with numerous wives in Paradise, but for every non-believer slain by him, the number of the houris is increased and their beauty magnified. When, therefore, Allah puts it into one's mind to die, it is well, if possible, to first lay in as large a stock of houris as can be secured. To the melancholic and the sexual psychopath "running amuck" therefore affords a desirable method of terminating life. The head and eyebrows of the fanatic are shaved by the hadjis, the genitalia are manipulated until erection has occurred, and then constricted around the base by means of a cord, and the whole bound against the lower part of the abdomen. Under sexual excitement, religious fervor, and possibly a dose of hashish, the "juramentado" now is ready to start in to kill all unbelievers—men, women, and children—until such time as his own life is terminated.

When a child is born to a Moro family it is put to one side and disregarded, while popular interest is directed toward the expulsion of the placenta. When this appears, it is carefully examined, and then repeatedly washed to the accompaniment of certain religious rites. It is then taken outside the dwelling and buried with much ceremony, and only after all the Mohammedan proprieties with regard to the placenta have been observed can the child receive attention. If it bleeds to death from the cord or succumbs as the result of exposure, it is evident that Allah willed that the child should not survive.

All true Moros should pass their alvine dejections into running water, as required by the Koran. Even if this is inconvenient of accomplishment, it must be done where possible, and ordinarily the house should be so situated as to permit this to be readily accomplished. If the only water course is the source of the domestic or village supply that need make no difference—for much should be done for the sake of winning the favor of Allah. Disease comes from Allah, not from microbes.

Among the Visayans, there is a strong belief in the, efficiency of "anting-anting" in the prevention and cure of disease and injury. "Anting-antings" of different kinds have different powers and uses. The "anting-anting" is a fetish or amulet which has no fixed form or type. It may be a piece of paper marked with cabalistic signs or a few meaningless words, or a piece of bone or horn, colored rags, bits of wood, or, in fact, anything. One never makes "anting-anting" for one's self, but secures them by present or purchase, usually the latter, from those who vouch for their efficiency. One "anting-anting" will afford immunity from cholera,another from smallpox, and a third from gunshot or other wound. Many of the late insurrectos wore anting-anting shirts of cotton, in appearance much like the Indian ghost-dance shirts, which afford absolute protection against rifle balls. The "anting-anting" must, however, be supported by faith, since without this it has no merit in averting disease, injury, and death. If one gets cholera and dies, or if a bullet finds its way through one, the fault was not at all with the "anting-anting," but because of insufficient faith. The same "anting-anting," with the support of proper faith, would have been an infallible protection, and the doubting Thomas who wore it is responsible for his own misfortune. Since "anting-anting" is a means of perfect protection against disease and death, it follows that there is no necessity whatever for doctors, medicines, and rules of hygiene. If one can buy guaranteed "anting-anting" from the man who lives in the next town for a Mexican dollar, why go to the foolish expense of paying several such dollars for a visit by a physician? Besides, "anting-anting" is a protection day and night, while at best a doctor is with one for but a short time only. Having possession of "anting-anting," which is an absolute protection against cholera, it is obvious that there is no necessity whatever for boiling water and carrying out other absurd and annoying sanitary regulations. All one needs is proper faith, and "anting-anting" will keep away all harm.

Among the more civilized Christian tribes of the country districts the belief in amulets and charms is strong, but these take the form of printed prayers, symbols, and pictures of saints. Disease is a retribution from God for sin, and medicines are less efficacious than prayer. In cholera time it is better to have processionals than to boil the drinking water, cook the food, and keep the person and surroundings clean. Prayer may induce the Deity to abate his wrath, but it is doubtful if attempts to stay the disease by human agencies is not impious as well as of little or no avail. Heaven having decided who is to die, there is obviously little use of disinfection and isolation in a community condemned to be scourged. Disease exists everywhere around one, but only those will sicken who are forsaken of heaven. A sacred emblem over the doorway is known to be potent in keeping disease from entering the house. Heaven may be propitiated by the prayers of multitudes, and hence when a community is attacked, all should flock to the places of worship. If the disease is very severe, the place is plainly accursed, and all who can should flee therefrom to other communities.

To the Negritos, disease is due to possession by evil spirits. The person so affected is, however, a source of danger to others, since the evil spirits in possession of his body and surroundings may also enter into the bodies of those in the immediate vicinity. This danger is especially great if the disease is liable to result fatally. It is a matter of safety, therefore, to desert the moribund. The dead body may be buried, but it is frequently advisable for the survivors to desert the habitation, conceal the approaches thereto, and build a dwelling elsewhere. Certain medicines may be of value, since it is known that they are so repugnant to the evil spirits that the latter may prefer to take their departure.

These various beliefs obviously have a powerful effect upon the practice of medicine and surgery, and the carrying out of sanitary reforms among the wholly diverse tribes of the Philippine Islands. Everywhere outside of the larger towns, modern medicine is opposed by incredulity, superstition, and fatalism. The latter is particularly hard to overcome, and the ideas and customs handed down for generations cannot be overcome in a day. Religious beliefs and those regarding the cause and treatment of disease seem to be almost inextricably associated with each other, from the fairly intelligent Christian native to the primitive pagan savage roaming the forests. There is no such thing as a Filipino nation, and probably a more heterogeneous group of peoples in the same area, entirely distinct in appearance, race, customs, and ideas, can not be found outside these islands. In the larger towns will be found many educated Filipinos, but the number of such, in proportion to the total population, is insignificant, and they are too few to leaven the whole. The thing to do is not to expect too much from the present, but to build for the future. Education is the only thing that will raise the natives to a higher level, wean them from superstition, and place the practice of medicine and sanitation on a satisfactory basis. The hope of the islands, in a medical way, lies with the children, and the American Government is well performing the herculean task of their education. As a whole, the Filipino peoples desire to learn, and the thousands of school children carry back into their homes much more than the knowledge gained from books. The mode of life of the American teachers and officials is noted, their advice asked in many things not in the lessons, and gradually a change for the better is taking place. As time goes on, customs are being modified and ideas are changing, and with the growing up of the present children tremendous sanitary improvement will be made through the islands as a whole. The United States has some tremendous problems to solve in the Philippines, and of these the sanitary questions are by no means of least importance. Education by precept and example is the only way by which this can be accomplished, and the government is doing magnificent work to this end. No peoples can be relied upon for support in matters which they do not understand, and the practice of medicine and sanitation will not be appreciated until these peoples have been instructed in their value. The due appreciation of rational medicine also depends upon the Christianization of the pagan tribes, and the education of the others that epidemic disease is not

a punishment from God, and as such unpreventable. That the latter can be done without destroying religious faith is shown in the United States, where there is no conflict between rational medicine and Catholicism. For this reason the establishment of American bishops and the introduction of American priests, who can be counted on to throw their influence in favor of modern medicine and sanitation, is bound to be a factor of the first importance in the sanitary regeneration of the Philippine peoples.

OUR LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

ANTHRAX—SMALLPOX—ANGLO-SAXON "CONSERVATISM"—CURABILITY OF LEPROSY

AUKLAND, N. Z., November 12, 1903.

SINCE I last wrote anthrax has made its appearance in New Zealand. Several cases have occurred in the rural districts, one of which has been brought up to the Auckland Hospital. I had, through the courtesy of Superintending Medical Officer Dr. J. C. Collins, the opportunity of seeing a number of beautiful preparations of the anthrax bacillus obtained originally from the patient, from cultures of the bacillus, and from the blood, liver, and kidneys of mice poisoned by inoculations from the pure cultures. Dr. Collins is an enthusiastic bacteriologist. It is believed that the disease originates from bone-dust imported from India, which is brought here in large quantities. It was supposed to have been properly sterilized before export, but evidently some carelessness has been shown in the process. Very energetic measures have been taken by the Agricultural and Health Departments to stamp out the disease, and sterilizing stations are being erected by the Government at the chief importing ports.

The smallpox scare has passed away. This disease, which really seemed to have obtained a firm footing in Tasmania, has now entirely disappeared. It must be from some quality in the air, unfavorable to the spread of the disease, for it certainly is not from vaccination, which is most imperfectly performed all over Australasia. It is curious how long the prejudice against vaccination lingers. The diseases which, in rare instances, were propagated by inoculation from diseased vaccinifers, cannot be produced now that calf-lymph is used, and human vaccine, absolutely prohibited. Yet we find the antivaccinators as furious as ever. *Quare fremuerunt gentes?*

We are expecting a visit from Dowie very shortly. We know him of old. He was here some eighteen years ago. He is certainly a very powerful hypnotizer, and it is by hypnotic suggestion that he effects his cures. I was employed by one of the principal New Zealand dailies to investigate his cures. I found none that could not be explained by hypnotism. But then hypnotism has a much wider range than most of our English-speaking physicians dream of. It is much to be regretted that so few—so very few—ever study the action of hypnotism as the French and Germans do. However, this is one of those subjects about which it is useless to write and equally useless to speak. The typical "Anglo-Saxon," as he delights to call himself, whether he dwells in America or in England, is the stupidest human animal to be found in the world. I have had considerable practical experience of negroes, natives of the East Indies, both Mahometans and Hindoos, natives of Polynesia, of China, and of all the countries of Europe, but none of them even approached the "Anglo-Saxon" in downright impenetrability to new ideas.

Take, for example, the curability of leprosy or cancer. I was sent more than thirty-five years ago to investigate a certain reputed cure of leprosy said to have been discovered by a Dr. Beauperthuy of Cumana in Venesuela. I was then occupying an official position, and was sent officially by the then Governor of Trinidad and by the Secretary of State for the Colonies. I reported a number of cases which I had examined, some unfavorably and some favorably. Some were unquestionably cures, if they had originally been suffering from leprosy. I was sent a second time, a year after. I tried the treatment myself and was perfectly successful in one rather advanced case and easily cured some commencing ones. My reports were presented to the British Parliament by command of Her Majesty. Hardly any professional paper noticed them. No proper trials are made of the system, and leprosy is still looked upon as incurable. I, personally, having been physician to a leper asylum, and examined and made notes of hundred of cases, am as convinced that leprosy can be cured as I am that pulmonary consumption can be cured. But it is of no use writing or talking. It is the same with cancer. If you cure a case which was admitted by everyone to be cancer, then it was *not* cancer, because if it had been cancer, it could never have been cured! Same with lupus exedeus. Instead of worrying patients with the Röntgen rays for months, lupus of the very worst kind is invariably cured in four or five weeks by the use of a drug which is in every pharmacopœia in the world. It is of no use to publish cases; no one believes them. A long life's experience has taught me that (with the rarest exceptions) unless a man has plenty of money to back him up, unbounded effrontery, and untiring perseverance and energy, he can never succeed in getting any mode of treatment adopted which shocks the prejudices or is contrary to the traditions of the profession.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Dec. 24, 1903.

Diffuse (Combined) Degeneration of the Spinal Cord.—E. W. Taylor and G. A. Waterman report two cases of this nature. In the first case, the most striking accompanying condition was general arteriosclerosis; in the second case, a fatal anæmia of the pernicious type. The lesions in the first case, though in general similar, were much more diffuse in character than those in the second, and more widespread, though less compact. Some authorities have thought that the converse is apt to be the case. The writers are, in general, strongly inclined to the view that anæmia, arteriosclerosis, and the various other concomitant conditions associated with this now well-deprived type of nerve degeneration are not etiologically significant. They think that a common but as yet unknown cause lies behind, which may be called a toxæmia They believe that these combined lesions may be regarded as either systemic or non-systemic, rather than as a mixture of the two.

Journal of the American Medical Association, Dec. 26, 1903.

Simple Method of Treatment of Hæmangioma.—Carl Beck of Chicago describes a method of treatment of nævus which he has employed a number of times with success. The method consists in the general principle of transforming the masses of vessels gradually into connective tissue. Gradually means in several sittings. This is done by a subcutaneous suture. A thread of catgut is passed in a zigzag manner, first below the skin, then underneath the base of the tumor; then, again, underneath the skin, underneath the tumor, etc., until the tumor mass is included in this continuous suture. This suture is drawn tight and closed at the point of the entrance of the needle. In this manner the circulation is shut off within the tumor, but no gangrene follows, inasmuch as some blood can yet reach the parts not included in the suture. After about a week the mass of the tumor seems much smaller. The normal epidermis, however, outside of it, which had been stretched, sometimes to considerable tension, becomes soft and elastic again and grows. This procedure is repeated until the tumor has been diminished to the smallest possible nodule of connective tissue, and the healthy skin enlarged to the utmost. Then the hard connective masses are excised and the borders united. If the tumor is growing in patches, the islands of normal skin will often be seen to enlarge within a few weeks to twice and three times their former size.

Medical News, December 26, 1903.

The Treatment of Some Diseases of the Eye by Warm Medicated Sprays.—David T. Marshall states that spraying with warm medicated sprays is indicated in almost all diseases of the conjunctiva, as acute catarrhal, chronic, epidemic, gonorrhœal, trachomatous, and phlyctenular conjunctivitis; in diseases of the cornea, as ulcer, infiltration and interstitial keratitis, and in iritis. The method used is as follows: A steam atomizer, such as is commonly used in spraying the throat, is filled with water, the alcohol lamp is lighted and a solution of the remedy indicated is put into the cup. The patient is seated close up to the atomizer. When the spray is well started, the lower eye-lid is pulled down, the eye held wide open and the spray is directed first into one eye and then into the other. The treatment lasts from five to ten minutes. After spraying, the eye may be touched with bluestone or alum stick, or applications of drops or ointment may be made as is indicated. These agents seem to act more effectively after the warm spray.

On the Reflex Eruptions of the Skin from Morbid Alterations in the Male Urethra.—A. Ravogli declares that the affections of the skin which originated from chronic disturbances of the urethra, are of a reflex nature and can be reduced to herpes and pruritus. In cases of herpes progenialis the writer makes a thorough examination of the urethra, and he has always found a condition of chronic posterior urethritis with all its complications. In cases of relapsing herpes he states that it is necessary to pay attention to the condition of the urethra and its glands, for they are quite often the cause of the persistence of

the herpes. The local treatment of the herpes is simple. Generally, washing with soap and water, and when dry, the application of absorbent powders, talcum, rice, oxide of zinc, bismuth, etc., give good results. When there is some necrotic condition of the epithelial cells at the bottom of the excoriation, the writer touches up the surface two or three times with a solution of nitrate of silver—from 3 to 5 per cent. He does not approve of the application of salves. Pruritus may affect the anus, perineum, and scrotum. In most cases these regions are affected with eczema, excoriations, and rhagades. It is often doubtful as to which affection has the precedence. The writer believes that pruritus is the first. His observations have led him to think that the cause of pruritus is to be found in the condition of the prostatic urethra. In treating this affection, massage of the prostate, or stripping of this gland is of great benefit. It removes the secretion from the body of the glands, thus diminishing the distention locally, the use of ichthyol gives relief from the itching. It also heals up the excoriations. In case of infiltration, the introduction of a sound covered with salve composed of 25 per cent. ichthyol in vaselin has often given good results. This treatment cannot be used more than once a week, and then with caution. After the excoriations are healed and the itching has diminished, application of the following ointment is advised: Benzoin, 5; vaselin, 70; zinc oxide, 25. When the skin has become normal, the treatment is finished by bathing the perineum and scrotum with a carbolic-acid lotion. When dry the skin is covered with rice powder or amylum.

New York Medical Journal, December 26, 1903.

Treatment of Typhoid Fever with Castor Oil—According to C. C. Bass, antiseptics in typhoid are too inert to be of any practical value. He believes in purgation. The diarrhœa of the disease is an effort on the part of nature to remove toxic products from the system. If cases are taken early enough before the diarrhœa sets in and the bowels are cleared out often enough with castor oil, there will be no diarrhœa, This clearing out removes toxic products and thus prevents absorption with its fever, etc. The oil is superior to salines which are absorbed into a system already overloaded with abnormal bodies, and by the elimination of the salines, additional work is already put on the skin, liver, and kidneys. The author's experience is based on seventy-nine cases, all of which recovered. Relapses occurred in four. In the majority of instances no medicine whatever was given except the oil. Abundance of pure water was allowed. Fluid diet was persisted in. Hemorrhages occurred three times. Bass advises the use of pure oil every twelve hours, regardless of the stage of the disease. The dose should be so regulated as to cause one or two movements, and will vary from one to eight drachms, depending upon the patient, the stage of the disease, and the condition of the bowels. This should be continued through all stages of the disease.

Laryngeal Complications in Typhoid Fever; Report of Case; Tracheotomy; Recovery.—H. Dupuy gives a summary of the literature of this subject and narrates his own case, that of a woman of twenty years. At about the end of the fourth week, signs of laryngeal stenosis appeared. Laryngoscopical examination showed the cords fixed in the median line with only the slightest separation along their posterior borders during inspiration. This was referred to ankylosis of the cricoarytenoid articulations. A high tracheotomy was done and relief ensued. Four hours later the trachea filled with blood-clots from a source that could not be determined. A later attack of heart failure was also controlled and the patient recovered. Ten days after operation the cords began to move, and three days later the larynx was able to carry on both its respiratory and phonatory functions. The author's general conclusions are as follows: Twenty-five cases collected from a period of fifty-eight years give evidence, bacteriological and clinical, strongly supporting the view adopted by the majority of observers, that the laryngeal involvement in most instances is a direct typhoid infection. A high death rate, as shown by statistics, when this complication exists, teaches the salutary lesson of always examining the larynx when the danger signals of hoarseness, dyspnœa, or dysphagia set in. The favorable results which follow operative intervention offer such a contrast to the high mortality without operation that there can be but unanimity of opinion as to its propriety. Tracheotomy is the most approved, because in most cases the only possible surgical procedure which can save life.

Fat Necrosis and Report of a Case.—The patient of V. B. Jackson was a man of fifty-six years. After unusual fatigue from a long walk and irregularities in diet. On the second day thereafter he was attacked with chill, intense nausea, vomiting, severe pain in the epigastrium, constipation, and slight fever. These symptoms continued with varying severity for some days and the patient then became jaundiced. Abdominal examination showed a distinct tumor midway between the ensiform cartilage and the umbilicus. It was about the size of the fetal head, somewhat movable and very tender on slight pressure. The patient's condition justified an exploratory incision. The subcutaneous and subperitoneal fat was found to be unusually thick. The latter was so great and contained arteries and veins of such size that we believed, for a moment, it must be omentum. This proved not to be the case, however, and upon incising the peritoneum, the large mass at once presented itself, which was no smaller than the previous palpation and percussion seemed to show. There seemed to be no disease of the abdominal wall fat, in spite of the extensive disease on the inside which involved a considerable portion of the small and large bowel with their omentum and mesentery. The transverse colon lay in a sulcus at its upper part, the duodenum and ileum being intimately attached below and the excessive fat of their omentum and mesentery, which was diseased and lumped together, apparently made the bulk of the mass. The thickened gastrocolic omentum was broken through at the left side of the tumor, to reach the pancreas, which was found to be somewhat enlarged and distinctly attached to the tumor mass by a thick pedicle. Gall-bladder, liver, and spleen normal. The prevailing opinion among the pathologists who examined a piece of the mass was in favor of fat necrosis. The removal of the entire tumor was deemed impracticable and the abdomen was closed. The patient made a good recovery, and one year later was reported as being well. The tumor seemed to disappear. It was considered to be due to a subacute pancreatitis and the initial acute symptoms were referred to a gastroduodenitis.

American Medicine, December 26, 1903.

The Islands of Langerhans in Congenital Syphilitic Pancreatitis.—Richard M. Pearce states that the histologic picture of the lesions of congenital syphilitic pancreatitis shows a peculiar relation between the islands of Langerhans and the newly formed tissue. This condition has not been generally recognized. It offers evidences in confirmation of our newer ideas concerning the anatomical and physiological independence of these structures. In all of the ten specimens which the writer reports, the lesion is of the advanced sclerotic type, with almost complete disappearance of the glandular elements. The early stages with infiltration of plasma and lymphoid cells is not seen. The most striking feature is the persistence of the islands of Langerhans, despite the general destruction of the glandular acini. The islands stand out prominently throughout the dense fibrous tissue. They are often surrounded by denser whorls of investing stroma, but are apparently uninjured. Here and there are fragments of gland tissue. In the pancreas of the third month, the islands are still connected with the acini by solid processes of cells. The proportion of connective tissue at this time is very great. Rapid glandular growth does not occur until the fifth and sixth months. Any disease of the pancreas occurring at this time would influence the development of the organ. Evidence of this faulty development would be present at any later stage of the lesion. This appears to be the case in the lesion under consideration. The general microscopical picture of the normal pancreas at the end of the third month is very similar to the syphilitic organ at the sixth or seventh month, except that the latter has a larger proportion of connective tissue. It seems justifiable, says the author, to conclude that the syphilitic infection occurs at the period (third to fourth month) when the islands are still connected with the gland tubules, and that the newly formed tissue causes atrophy of the gland acini, but spares the more resistant islands. The ultimate factor in this resistance of the islands is their abundant blood supply. This supply, the author has demonstrated, is not altered in syphilitic pancreatitis.

Sarcoma of the Abdominal Wall, and Probably of the Pelvic Viscera, Which Has Disappeared under the Use of the Röntgen Rays.—George Erety Shoemaker reports this interesting case: The patient when first seen by the writer was aged thirty-six, had been married twenty years and had had three children. There was no specific history and no enlargement of the glands in the groin or occiput. She was referred to the writer in November, 1902, on account of a growth in the lower abdomen. There was a history of irregular hemorrhage from June to August, 1902, followed by enlargement of the abdomen and an inflammatory attack which began August 7, with a chill followed by temperature of 104° and perspiration. There was no vomiting and on diarrhœa. The soreness, which had continued ever since, was worse in the left ovarian region. Examination showed a swelling

in the median line just above the pubic bone, and apparent ly continuous with it. This swelling had appeared during the illness already described three months before. It had been so sensitive that a large amount of opium was necessary for its relief. This mass was about two and a half inches in diameter, dark red, smooth, rounded, and immovable. It appeared to infiltrate the tissues at the insertion of the recti muscles into the pubic bone. There was some tenderness. The skin was not broken. The patient suffered from almost constant severe pain in the lower abdomen, bearing down in the bladder, and frequent urination with pain at the end of the act. As a pelvic mass was detected to the left of the uterus abdominal section was performed above the limits of the superficial tumor but below the umbilicus. The rectum, uterus, and the left tube and ovary were massed together by an apparent infiltration, but had a certain range of motion. The tumor in the lower abdominal wall was united to this mass by a process of thickened tissue a little to the left of the median line. The whole appearance suggested a new growth, which it was thought unwise to remove. The incision was closed and a cut made directly into the suprapubic growth. Examination of the piece removed for that purpose showed that the mass was sarcoma. Treatment by the Röntgen ray was begun after the healing of the upper wound. This treatment continued for about nine months in all. The total number of exposures was forty-nine. The improvement was remarkable. The pelvic enlargement rapidly disappeared. A year after coming under observation the infiltration of the abdominal wall was entirely gone. There was no pain or soreness. The uterus was in normal position and was freely movable. The patient had increased in weight—sixteen pounds during the past five months. She was sleeping and eating well. She stated that she was feeling better than she had for the last five years. The question arises in consideration of this case as to whether the pelvic mass and the tumor in the abdominal wall were of the same character. This mass, if not sarcomatous, could only have been inflammatory. The writer does not believe that the condition was the result of inflammation. The result in this case is so far more favorable than those usually reported.

The Lancet, December 12, 1903.

Inoculations with Haffkine's Plague Prophylactic.—C. E. P. Forsythe reviews the results in 30,609 cases. Of this number of patients but 329 were attacked by the plague, and of these 50 died, a mortality rate of a little over 15 per cent. Some of the patients attacked were inoculated in the incubation period of the disease. The only outward consequence of the inoculation was the development of abscesses at the site of inoculation in sixteen patients. All but one of these were traced to a particular bottle of the remedy, which in some unknown way had become contaminated.

Some Observations on Over 6000 Inoculations against Plague.—This paper records the experience of J. W. Miller in the Punjab. Inoculations were generally made in the left arm. Strict asepsis was observed. The author thus describes symptoms following the operation. Aching begins at the site of inoculation a short time after the operation and gradually increases so that as early as one hour after inoculation some pain is felt on movement and in addition some stiffness and a feeling of heat in the arm. These symptoms gradually become more marked, and usually the local symptoms are most pronounced the first evening after inoculation, assuming that the person has been inoculated in the morning. A rise of temperature is perceptible a few hours after inoculation. One abscess resulted out of the entire number of inoculations. It is not stated whether or no the inoculations were universally successful in averting the plague.

Symptomatic Parotitis Following Strangulated Hernia.—The patient of F. B. Jeffcriss was a woman of sixty-eight years with strangulation of an umbilical hernia of some years' duration. Operation was without incident. On the fourth day after, the patient who had been doing well, had a fever, dyspnœa, and dysphagia. The right parotid was considerably swollen, and later the swelling extended to the right submaxillary. She had been a sufferer from chronic bronchitis, which seemed to take a fresh start. Respirations were forty per minute and her general condition very bad. She died on the fifth day after the operation, twenty-four hours after the onset of the parotitis to which the fatal result is ascribed by the author.

Deformity of the Heart in the Mongolian Imbecile.—Three cases are described by C. H. Fennell, as follows: Case 1. Male, aged twenty-seven years, a low-grade imbecile, in good health, and not at all anæmic. The area of cardiac dulness extended one and a half fingers' breadth to the right of the sternum; on the left side it reached the nipple line. A to-and-fro murmur was heard in the upper three intercostal spaces on each side of the sternum, but best in the second left space and better along the left sternal border than the right. There was no cyanosis or clubbing, and the patient has had no syncopal attacks and his heart worked adequately. Case 2. Female, aged nine years, a low-grade imbecile of well-marked Mongolian type, in fair health but subject to catarrh. The area of cardiac dulness extended one and a half fingers' breadth to the right of the sternum; its left limit was half a finger's breadth inside the nipple line. There was a diastolic bruit at the left base, replacing the pulmonary second sound and best heard in the second left intercostal space. No systolic bruit was audible. The child showed no cyanosis or clubbing, but the circulation in her extremities was poor. She was rather torpid and inactive and showed no signs of cardiac failure. Case 3. Male, aged thirteen years, a medium-grade imbecile in good health. The area of cardiac dulness was not increased toward the right; on the left it extended beyond the nipple line by a finger's breadth. A double murmur was present at the base and was heard better on the left side. There was a loud apical systolic murmur heard also all over the left chest and to a less extent over the right chest also. A systolic thrill was felt at the apex. There was no cyanosis or clubbing and the heart acted well.

The Lancet, December 19, 1903.

Persistent Superficial Nasal Hyperæmia Cured by the Removal of Adenoids.—The patient of Wyatt Wingrave was a man aged twenty-one years who, for two years, had complained of intense and persistent redness of the nose. The latter was not obstructed, but there was a large crop of adenoids. The supranasal vein was quite prominent. The adenoids were removed as was also the nasal abnormality. The relation of adenoids to an enlarged supranasal vein is of interest and admits of several interpretations: First there is the mechanical, in so far that the adenoids themselves directly interfere with venous return, thereby producing the prominent supranasal venous arch in infants, so often the subject of superstitious dread. Further, again, their interference with breathing leads to a general increase of venous pressure which the vessels in question specially show. A second view is that the adenoids are responsible indirectly by causing a reflex inhibition of a local vasomotor influence. This may be the interpretation in the present instance, while the first view will be more applicable to children.

After History of a Case of Extragenital Chancre.—The patient of S. Snell, a young woman of twenty-one years, was first seen in 1882. There was a chancre at the inner canthus, caused by infection from a syphilitic child for which she cared. Marriage was contemplated and was consummated (against advice) about nine months later. She was seen again by the author some ten years after. She had had five miscarriages, finally giving birth to a full-term child, which remained healthy until it was ten months old, when it had convulsions and became paralyzed on the left side. The mother had remained in surprisingly good health. Later the child had an interstitial keratitis and other stigmata of syphilis. Finally in March, 1903, the mother came under treatment for interstitial keratitis. The author regards the case as of great interest for many reasons, among which are the following: (1) the situation of the chancre; (2) the characteristic history of the patient's children; (3) the fact that one of the children came under treatment for typical interstitial keratitis: and (4) the circumstance that the patient herself suffered from interstitial keratitis, which is only rarely met with in instances of acquired syphilis, and which is additionally interesting in this case from the complete history that can be recorded and from the late appearance of the keratitis.

A Case of Arterial Thrombosis of Gonorrhœal Origin.—The case is reported by F. C. Moore, his patient being a young man of twenty years, suffering from early dry gangrene of the leg. He had had a chill four days before being seen, his left leg had become cold and painful, getting progressively worse, and he had taken to bed. A purulent discharge escaped from the urethra. The leg soon presented a discoloration, the right leg soon began to become affected as the left had been. His general condition grew progressively worse and he died on the eighth day after his initial chill. Autopsy showed the aorta free as far down as the renal branches, but below that situation it was completely occluded by firm, reddish-gray, adherent thrombus. The upper end of the thrombus was inclined obliquely from the orifice of the left renal artery above down to the wall of the aorta below the orifice of the right renal artery. The left renal artery itself was also occupied by similar but rather softer thrombus extend-

ing into its several subdivisions in the hilum. The right renal artery was free from thrombus and appeared to be quite healthy. Below, the thrombus continued in its completely obstructing form into the common iliac arteries and along these into the external and internal iliac arteries on both sides. In the external iliac arteries it extended on the left side into the common femoral artery, and on the right side to within half an inch of the pelvic brim. The internal iliac arteries and their secondary branches were similarly occupied by thrombus. The author advances two theories (inclining toward the second) of the mode of infection: (1) infection of small branches, possibly prostatic, of the internal iliac arteries and the development of an ascending gonorrhœal thrombo-arteritis; or (2) infection of the intima of the common iliac arteries by organisms present in the general circulation.

British Medical Journal, December 12, 1903.

The Behavior of Cancer within Nerve and Trophic Areas.—G. Lenthal Cheatle shows that the spread and limitation of cancer in the skin and muscles bear a marked relationship to the presence of nerves, and the absence of nerves where normally they previously existed bears a marked relation to the limitation of cancer. The writer cannot say whether cancer can genetically arise in a completely denervated area. This disease can exist for a considerable time in a completely denervated area, although it does not spread in that area. It is not alone rodent ulcer that follows definite areas. Benign, but diffuse, papillomata of the tongue show remarkable middle line limitations. Squamous epithelioma, beginning on the lip or elsewhere on the nasolabial region with remarkable regularity, covers the whole area, and apparently rather than leave that area it fungates.

On the Treatment of Cancer.—Lovell Drage concludes that: The condition which the treatment of cancer is designed to produce is first a leucocytosis; and secondly, a fibrosis in the tissue affected by cancer. In the case of pulmonary tuberculosis there is no difficulty in producing these conditions; in that of cancer much greater difficulty is experienced in advanced cases than in the case of tuberculosis. However, it is claimed that the treatment is soundly based, and that although it is quite likely that the best possible means of initiating the changes desired has not yet been found, it is only a matter of time for improvement in the details of treatment to be effected. Success in the treatment of cancer must depend to a great extent upon the physical condition of the patient, and to some extent upon the part of the body attacked.

Nature and Physiological Action of Radium Emanations and Rays, with Observations on Other Rays.—Dawson Turner states that the distinguishing radioactive properties of radium are that it gives off a radio-active emanation and three kinds of rays—*x*-rays, *b*-rays, and *y*-rays. It maintains itself constantly at a higher temperature than its surroundings, and it continually emits heat at an estimated rate of about one hundred calories per gram per hour. The emanation is of the nature of a luminous gas, which can be condensed by intense cold, and which imparts radioactivity to objects in its path. Though the microorganisms of certain diseases are not very susceptible to radium rays, the human tissues are. It is unsafe to carry radium about in the pocket. The chief physiological effects of radium, so far known, are: Effects on the skin, producing inflammations and ulcers. Effects on the nervous system, producing paralysis and death. Luminous effects produced in the partly blind. The radiations of radium have been tried in various diseases, and have been found in many cases to have distinctly beneficial effects.

The Parasitic Theory of Cancer.—H. G. Plimmer presents various reasons why he thinks we dare not at present give up the parasitic theory of cancer. During the last few years there has been an increase in the number of cases of cancer which is out of all proportion to any known general cause, except a parasite. There are also recorded many instances of relative increase in the frequency of cancer which may be called epidemics of cancer. These epidemics are easily explainable from the parasitic point of view. In many districts the death rate from cancer is abnormally high, and it varies greatly in the same district at different times. This seems to be explained only by the presence of a parasite, which in certain places and times finds better conditions of existence for itself. The disease has a predilection for low-lying damp districts, and especially for those which have both wood and water. Lately a number of facts have been brought forward showing its incidence in certain houses Certain authorities believe that the probable source of infection is often uncooked vegetables. There are certain definite bodies which are found in cancer. They are round and contain a very small, more or less central body, surrounded by a very delicate substance. These bodies have very definite reactions to certain stains. The living cells of the cancer should be examined in their own juices, or in serum, on the warm stage. The bodies previously referred to, are not to be found in other structures aside from cancer. It has been known for centuries that cancer is locally contagious—for example, between the upper and lower lips. The inoculation of cancer from animal to animal of the same species has been often successfully done. The writer then calls attention to the clinical course of the disease, its beginning in one spot, its extension to distant parts by lymphatic or blood ways, the cachexia out of all proportion to the extent of the disease, the spread by contagion, the occurrence in certain parts of the body, and its return after years of quiescence—all of these facts being explainable by the parasitic theory.

British Medical Journal, December 19, 1903.

Ovariotomy on a Patient Aged Seventy-nine Years.—Thomas North presents the history of this case. The patient was a widow aged seventy-nine years. She had had six children. She had had no illness of any kind till five or six years ago, when she noticed a swelling on the right side of the abdomen. This continued to increase. Recently, she had suffered much from a feeling of distention and shortness of breath. Operation was performed, and an ovarian cyst containing twelve pints of clear fluid was removed. The patient made an uneventful recovery, and now, four months later, is in good health, and going about daily.

Carboluria Due to Salol.—John Wm. Taylor reports this case. He prescribed salol in five-grain tablets for a woman of forty-three years suffering from flatulent dyspepsia. He ordered one tablet three times a day after food. After the administration of six tablets, the urine became olive green in color and gave a purple reaction with dilute liquor ferri perchloridi. The salol was discontinued, and thirty-six hours later all trace of carboluria had disappeared. There were no other symptoms. The symptoms of carboluria in this case, the author believes to have come on exceptionally soon.

The Etiology of Beriberi.—William Hartigan declares that his experience in Hongkong proves beriberi to be a place infection. He gives various instances to prove this fact: a batch of healthy Chinese carpenters were shipped from Hongkong to Aden for shore work. Within a month all suffered from beriberi, the rice consumed on the voyage and afterward, being the same as that eaten by other natives who were not attacked. Three successive batches occupying the same quarters were also stricken. The quarters were then thoroughly disinfected and a fifth lot lived in them with impunity. The writer relates other incidents which tend to prove the point which he emphasizes that rice eating is not the cause of beriberi.

Deutsche medicinische Wochenschrift, December 10, 1903.

Experimental Syphilis.—Metschnikoff and Roux inoculated a female chimpanzee with syphilitic virus and produced a characteristic hard chancre which appeared at the end of twenty-five days. A month later fifteen squamous pustules appeared on the body of the animal which also were typical in nature and persisted unchanged for a month. The animal died at about this time of pneumonia. Some of the virus had been inoculated on the penis and thigh of a male animal on the forty-fifth day of the female's disease, and on the thirty-fifth day the male displayed analogous local lesions. The animal died on the forty-fifth day without having presented any secondary syphilitic lesions, but the results in these two cases are sufficiently marked to allow the conclusion that much is to be learned concerning syphilis by experimentation on the anthropoid apes.

Can the Virus of Rabies Be Filtered?—Celli and Blasi made a solution from the brains and spinal cords of experiment animals by mincing the organs, mixing them with sand and expressing in a Buchner's press under a pressure of 300 atmospheres. The juice so obtained was diluted when necessary with distilled sterile water and infected with several loops of fresh virus. It was then filtered through the ordinary small Berkefeld's filters by the aid of a filter pump. Experiments were made both with street virus and with fixed virus. Nearly all the animals inoculated with this product died, only three out of twenty-three rabbits survived, and every one of four dogs died. A large proportion of the animals, however, did not display the usual symptoms of rabies, and after death no discoverable lesion could be found. The bodies considered by Negri as the parasites of rabies were found in the brains of one rabbit and one dog. The authors conclude that the virus is, under certain circumstances, susceptible of filtration.

Immunization against the Tubercle bacillus.—Friedmann has found that a certain tubercle bacillus which is

invariably fatal for turtles is without effect on guinea-pigs, and, furthermore, confers on them complete immunity against the human tubercle bacillus. Animals injected with the usual dose of virulent bacilli after a preliminary treatment with turtle tubercle bacilli not only did not die, but on autopsy the only lesion was an occasional small round-cell accumulation. The fact that guinea-pigs, the most susceptible mammals, can thus be treated with a variety of tubercle bacilli pathogenic for a poikilotherm, and rendered immune, leads to the belief that similar treatment can be carried out on all other warm-blooded animals with equally satisfactory results.

Berliner klinische Wochenschrift, December 7, 1903.

The Treatment of Articular Rheumatism with Menzer's Antistreptococcus Serum.—Schmidt treated fifteen cases of rheumatism that had resisted all other measures, with Menzer's serum. Regarding the results from the most objective standpoint, six cases showed distinct improvement, in four the results were doubtful, and in five there was no change. The author's conclusion is that the serum is not a specific one in the same sense as that of diphtheria is, but that it is impossible to deny that in certain cases it does produce favorable results. This is especially true of subacute and subchronic cases, while in the acute and chronic stages it is without effect. In practice the serum should be employed after the usual forms of treatment have been found ineffectual.

The Application of the Lowering of the Freezing Point of the Urine in the Estimation of Renal Function.—Zangemeister says that the value of direct observations of the lowering of the freezing point of the urine in determining the efficiency of the kidney is open to several sources of error. The recently discovered fact that in parenchymatous nephritis the kidney may be unable to excrete an excess of water introduced into the body may cause a urine to be passed the molecular concentration of which is greater than that of a normal urine. The degree of molecular dilution which can be produced by the administration of large amounts of water forms a useful guide in judging of the state of the kidney. The variations in the dissociation index of different specimens of the same urine is another source of error, for on diluting urine the molecular concentration calculated from the freezing point does not sink proportionately, owing to the fact that dilution causes the saline molecules to break up into ions which functionate as separate molecules and so simulate a greater degree of concentration than exists. This objection applies even to twenty-four-hour specimens. Urates may also be precipitated from the urine in cooling, so as to cause the freezing point to rise, and in concentrated urines the water tends in part to freeze first and to cause the freezing point obtained to be that of the unduly concentrated residue. These objections may be met by greatly diluting the urine till the "ideal" freezing point is reached which is not affected by any of these factors. In practice the author finds that according to the concentration of the urine examined a dilution of five to fifteen times permits the "ideal" freezing point to be obtained without any loss of accuracy through excessive attenuation of molecular composition.

Münchener medicinische Wochenschrift, December 8, 1903.

A New Method of Quantitative Pepsin Estimation.—Volhard says that the methods of determining the pepsin content of the gastric juice have heretofore been based largely on animal experiment, and have also assumed that the digestive power of peptic solutions is directly proportional to the amount of pepsin present. Schütz has shown that this is not so, but peptic digestion follows the law that x units of pepsin digest only $\sqrt{x}$ times as much as a single unit. Observations with Metts's capillary tubes have shown the various digestive products inhibit digestion to such a degree that constant results are obtainable only in dilutions of one to sixteen of the gastric juice. This dilution is so great as to make clinical application of the otherwise convenient Metts' method impracticable. The author's method, which is not given in detail, is based on the fact that when casein dissolved in gastric juice is precipitated by the addition of sodium sulphate, the acidity of the filtrate bears a constant relation to the amount of pepsin present and the time of digestion.

An Enriching Method for Typhoid and Paratyphoid Bacilli.—Lentz and Tietz have devised the following for typhoid and paratyphoid bacilli as an analogue to Koch's method of enriching cholera stools. The stool is mixed with double the amount of physiological salt solution. One to two-tenths of a cubic centimeter of the mixture are sown on an agar plate to which malachite green has been added in a proportion of about 1-6000, and on two litmus-lactose agar plates, as in the method of Drigalski-Conradi. After twenty hours in the incubator, if no typhoid colonies are found on the blue plates, suspicious colonies on the green plate are tested for agglutination. If the result is again negative the plate is flooded with 2 cm. of broth or salt solution, and one loop of this mixture sown on two large litmus-agar plates, after sixteen to twenty hours in the incubator these plates are searched for typhoid colonies. The method is equally applicable to the examination of urine. The property possessed by malachite green of inhibiting the growth of nearly all organisms except the typhoid and paratyphoid bacilli is very marked, the members of the colon group being especially susceptible to its presence, but as different specimens of the dye vary somewhat in nature, central tests on known cultures are first necessary to determine the proper concentration of the solution to be added to the agar plates.

Detection and Significance of Minute Quantities of Blood in the Stomach Contents and Fæces.—Schmilinsky says that the detection of macroscopically undiscoverable quantities of blood in the contents of stomach or intestine is receiving greater attention, and that distinct value attaches to it. Occult bleeding is frequent in ulcer and almost constant in carcinoma. Severe disturbances of motility also can produce such hemorrhages, but in other conditions they are rarely seen. The presence of blood alone is, however, not sufficient to establish the diagnosis, and the other symptoms must be given due weight. It is a sign of particular value in early carcinoma, while the disappearance of the blood after bland diet and lavage makes malignant disease unlikely. Negative results have less value than positive ones. The author has found a modification of the guaiac reaction the most satisfactory. The usual spectroscopic test for acid hæmatin may be improved upon by transforming the hæmoglobin into hæmatoporphyrin by the addition of an excess of concentrated sulphuric acid. The spectrum produced is sharp and easily recognizable, but the test is inferior to the guaiac reaction. The hæmin test is particularly unreliable. Owing to the danger of contaminating stomach contents with minute quantities of blood through abrasions produced by the tube, it is preferable, after two days of gentle purgation and diet free from meat or chlorophyl, to examine the fæces. The stool is made uniform in composition by trituration in a mortar, and a small portion (the size of a hazel nut) treated with one-third its volume of glacial acetic acid. It is then extracted with 10 c.c. of ether, and the separation, if necessary, facilitated by the addition of a few drops of absolute alcohol, or a little more ether. The ethereal solution is filtered and five drops of guaiac solution, and ten drops of ozonized oil of turpentine added. Large and moderate amounts of blood give the classical blue color, but this appears only after a succession of other shades has first been run through. Traces of blood may not suffice to carry on the changes to the final blue stage, and hence the formation of a deep green or brownish red is very suspicious, and should always be regarded as an indication for repetitions of the test with more concentrated material, or other stools, etc.

Lactic Acid Fermentation in the Stomach with Especial Reference to the "Long Bacilli."—Sandberg calls long bacilli those usually referred to as Boas Oppler bacilli, or the bacillus geniculatus. Various degrees of significance have been ascribed to these organisms which habitually outnumber all others in cases of gastric carcinoma with pronounced lactic acid formation. The author found two forms present in such stomach contents which differed somewhat in morphology and cultured characteristics, but which he was able to prove were the same organism. The parent type is composed of short rods, but as soon as they are able to exert their lactic-acid-producing properties or are in a medium in which other organisms are actively forming lactic acid they change to a longer form. These long and short types grow in distinctive colonies between which transitional forms may experimentally be produced. The predominance of the long bacillus in certain gastric disorders is due to the fact that they possess a special resistance for lactic acid which is not common to other fermentative bacteria. They are able to develop when lactic acid is present in the stomach contents in amounts sufficient to check the growth of all other lactic-acid formers, and therefore ultimately to outgrow all of these. The irregularities of the gastric mucosa produced by a carcinomatous growth also tend to form small collections of fluid differing in composition from the general secretion, and thus explaining instances in which the bacilli are present with but small quantities of lactic acid.—*Zeitschrift für klinische Medicin*, Vol. 51, Nos. 1 and 2.

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Sixteenth Annual Session, Held at Atlanta, Ga., December 15, 16, and 17, 1903.

J. WESLEY BOVEE, M.D., OF WASHINGTON, D. C., PRESIDENT.

AN address of welcome was delivered by Mayor Evan P. Howell, which was reponded to by Dr. George Ben Johnston.

After a brief report by the Chairman of the Local Committee of Arrangements, Dr. Willis F. Westmoreland, the reading of papers was begun.

A Study of the Prostate and Treatment of Prostatic Hypertrophy.—Dr. G. WILEY BROOM of St. Louis, Mo., exhibited a number of hypertrophied prostates that he had removed The author said that he had made approximately two hundred post-mortem examinations to investigate the condition of the bladder and prostate in each subject. He said it was generally believed by routine prostatectomists that all prostates had a capsule, but this was not true. His conclusions were: (1) The position of the urethra in the normal state was always in the floor of the bladder; but in urinary obstruction it was always elevated from an inch to an inch and a half or two inches above the floor of the bladder. (2) He took the position that normally there was no third lobe, but that segmentation took place behind the prostatic fissure in consequence of a hyperplastic process, this process occurring in the direction of least resistance—into the cavity of the bladder. (3) Only a small percentage of cases of hypertrophied prostate was responsible for urinary obstruction. (4) No matter how large the prostate became, it would retain its functionating capacity. It was not the organ which caused suffering to the patient. (5) By prostatectomy this functionating organ was mutilated or destroyed, and the bladder, which really caused the patient trouble, was left *in situ* without any operation having been performed on it. (6) In only a small percentage of cases could the prostate be enucleated. (7) It was unfortunate that the profession had reached the point of resorting to routine prostatectomy in all cases of urinary obstruction. (8) The commissure and capsule were obliterated in the fibromyomatous variety of prostate. In the adenomatous variety, if complete and permanent drainage was established, the prostate would shrink.

Dr. C. H. MAYO of Rochester, Minn., had operated by the median perineal method in over thirty cases after the manner of the Goodfellow procedure, and had been much pleased with the method and results.

Dr. W. P. CARR of Washington, D. C., had seen but one prostate which there was any difficulty in peeling out of its capsule. Cases of hypertrophied prostate should be operated upon earlier, before the bladder became infected. Prostatectomy in healthy men had a very small mortality; but in those who had infected bladders, who had Bright's disease, or atheromatous arteries, it was a serious operation.

Dr. Broom, in closing, deplored the tendency to do routine prostatectomy regardless of the actual pathological conditions of the parts.

Œdematous Encephalitis.—Dr. W. P. CARR of Washington, D. C., called attention to a condition of the brain that he had encountered quite frequently when operating for cerebral epilepsy and for suspected cerebral abscess following mastoid disease due to la grippe. This condition he called œdematous encephalitis. It was apparently so much benefited by opening the skull and draining the excessive serum from the brain, that it deserved careful consideration. He reported four cases. It was impossible to say in most cases whether the œdematous encephalitis was caused by injury or by the poison of influenza, or whether it was a lesion of epilepsy. He had not been able to find any cases in the literature in which œdema was noted as a marked feature. In cases of severe cerebral symptoms following influenza or blows upon the head, when the symptoms persisted or became worse after weeks of medical treatment, he thought that exploration was justifiable in the hope of finding œdematous encephalitis or some other condition that would be benefited by operation. In operating for œdematous encephalitis he recommended that a large osteoplastic flap be cut with the De Vilbiss craniotome over the site of any injury that might be suspected as a cause, or over some location indicated by the symptoms. If the symptoms furnished no local indication, and there was no local injury, then the flap had best be turned down in a convenient place, say the upper parietal region. The exposed membranes and brain substance should be examined carefully, and if they presented an œdematous appearance, a grooved director should be introduced into the brain substance carefully in several places, and the serum drained off until the brain assumed a normal appearance. A small soft drainage tube should be inserted just through the dura into the arachnoid space and left in place as long as there was a copious discharge of serum. This tube might be brought out through one of the small trephine holes made for the introduction of the De Vilbiss instrument, and stitched to the skin after an osteoplastic flap had been replaced. If the head was carefully shaved and scrubbed, and all proper antiseptic precautions taken, this operation was almost free from danger; and if only a small percentage of the serious cases could be cured in this way, the operation would be justifiable. He had been encouraged by his limited experience to believe that surgeons might hope for recovery or great improvement from this operation in many otherwise hopeless cases of epilepsy and of progressive brain disease due to trauma and influenza.

A New Device and Method for Intestinal Anastomosis.—Dr. W. P. CARR said he had devised a method of intestinal or gastrointestinal union by small silver clamps, which he thought were more easily and quickly applied, and had none of the objectionable features of the Murphy button. The clamps were exhibited. The method consisted in clamping the inverted edges of the gut from the inside, in the manner indicated by drawings which were passed around by the author. The clamps will hold well and make an air-tight closure. They were applicable to any sized intestine or wound. They left a large opening in the lumen of the bowel, and passed out as easily as watermelon seeds. The edge and corners of the clamps were smooth and rounded. They had small teeth to prevent slipping, made by simply indenting the metal; but these teeth were not long enough to pass through the entire thickness of the bowel. The clamp might be applied with any suitable flat broad forceps, but it was better to have a forceps with a slight ridge to keep the clamp from slipping. He had used these clamps in one case of resection of five inches of gangrenous ileum caused by strangulated hernia. The man recovered, and most of the clamps were recovered between the sixteenth and twenty-first days

Dr. C. H. MAYO said he and his brother (William J.) had operated on many cases of epilepsy and traumatic insanity, and he could corroborate what the essayist had said regarding œdematous encephalitis. Treatment by drainage came the nearest to the solution of affording this class of cases relief.

Dr. I. S. STONE of Washington, D. C., mentioned a case, in referring to Dr. Carr's device, in which gastroenterostomy was performed about a year ago with the aid of the Murphy button, but the button had not yet been passed. In another case of diverticulum with obstruction the button was used, but the woman was still carrying it with some anxiety. Thus far, however, there were no symptoms of intestinal destruction from the retention of the

button. He complimented Dr. Carr on the ingenuity and originality of his device, and said when an opportunity presented itself he would use it.

Dr. Guy L. Hunner of Baltimore, Md., objected to the use of all mechanical devices, and favored suturing the intestine; although he thought the simple device exhibited by Dr. Carr would enable surgeons to do intestinal anastomosis rapidly.

Dr. J. Garland Sherrill of Louisville, Ky., advocated suturing the bowel in preference to the use of all mechanical devices. In his intestinal work he preferred silk.

The Surgical Physiology of the Lymphatic System.—Dr. C. H. Mayo of Rochester, Minn., said that a study of the lymphatic system readily explained many normal physiological as well as pathological processes. The subject was deservedly receiving more attention from surgeons who now generally recognized that aside from acting as the general absorbent system, it was constantly engaged in maintaining nutrition as well as defence against pathological processes. All tissues were provided with lymph vessels and glands in direct proportion to their exposure, activity, and necessity for repair. The tissues of the body were constantly bathed in lymph, which fluid, similar to and derived from the blood plasma, must all pass through the lymph vessels and glands. In the glands the lymph was exposed to the direct action of the leucocytes which were there found in great abundance. It was in the glands that infection was checked and destroyed, or it might possibly overpower the gland and develop local growth. An enlarged gland was an evidence of a local struggle of a defeat. The lymph system undoubtedly performed a great function in draining the ductless glands. Considering the lymph supply of certain organs, it was found that the brain was deficient in lymphatics in its structure, the arachnoid serving this purpose upon its surface. Hemorrhages into its structure became cysts from lack of absorption, and infections in its substance caused but little temperature or general disturbance, except from pressure. The liver and kidney showed the same condition in a less marked degree. The lungs, rich in lymphatics, gave constant temperature from infectious diseases. Chills usually signified the direct delivery of accumulations of infection into a vein. In certain diseases resulting from a loss of equilibrium between the production and absorption of fluids, one set of lymphatics was substituted for another by operation, as in glaucoma and hydrocephalus. When lymphatic conditions were considered in connection with surgical work, it was found that there was a real principle involved in drainage, whether it be internal or external. (1) Rest by splints, pressure, dressing or bed, to quiet the circulation: (2) by elevation to reduce arterial supply and favor venous and lymphatic return; (3) by massage to break up coagulated exudates and enable the lymph vessels to remove the exuded material; (4) moist dressings favor the escape of exudate from open wounds, and also favor the lymphatic circulation in closed injuries; (5) adjuncts to drainage in the use of solutions having affinity for moisture acting by osmosis, as glycerin or alcohol; (6) wound drainage could be accomplished by the open method with or without secondary suture; (7) by separate incision; (8) by wicks, capillary or tubular drains, or gauze packs, as mechanical aids.

Early Diagnosis of Cancer of the Uterus.—Dr. F. F. Simpson of Pittsburg, Pa., said the great body of the medical profession saw but a single case of cancer during the time they were treating hundreds of other afflictions, and naturally looked upon that malady as being relatively rare. As a malady, it was infrequent; but as a cause of death its frequency was appalling. Early in 1900 a note was addressed to the health departments of American cities, with an aggregate population of ten million, requesting a tabulated statement of deaths from cancer and from all causes during each year of the preceding decade. Statistics showed that of every fourteen people who reached the age of thirty, cancer would claim one as its victim. Bearing more directly upon the subject of cancer of the uterus, however, was the distressing fact that of every twenty-eight women who passed the age of thirty, one would be the victim of this disease. The paper was largely statistical, and the author closed by saying that the day was fast approaching when well-informed women of the cancer age would seek protection by regular quarterly examinations. Early diagnosis would then be the rule in cancer of the uterus as it was in appendicitis to-day.

Fracture Dislocation of the Spine.—Dr. J. Shelton Horsley of Richmond, Va., reviewed the opinions of several authorities on the treatment of this lesion. He recommended that in treatment individual judgment should be used as in other surgical operations. He emphasized the similarity between the injuries of the spinal cord and injuries of the brain so far as treatment was concerned, and called attention to the fact that without an operation, or a post-mortem examination, it was impossible to tell by symptoms alone when the cord was completely destroyed. He advocated the plan of McCosh, to operate in all cases of complete paralysis below the injury, unless there was improvement within twenty-four hours after the injury. When the trauma was especially marked, he operated sooner. He pointed out that the danger of delay lay in degenerative changes in the spinal cord, which set in soon after the injury. Early operation might arrest this degeneration. He reported six cases, in two of which the injury was received several years before he saw the patient. In one there was a forward dislocation of the axis and atlas from the third cervical vertebra. This was demonstrated by an *x*-ray picture. The patient had paralysis of the muscles of the arms, body, and thighs. There were disturbances of sensation of various degrees over the body and limbs. He reported two other cases in which fatal results rapidly followed the injury. One was from a gunshot wound, and the other was the result of a fall on the shoulder in which there was a fracture-dislocation in the lower dorsal region. The last two cases he operated upon, in one there was an injury at the lower dorsal region, where the whole of the dorsal spinal column was dislocated forward upon the lumbar spinal column. The spinous process of the last dorsal vertebra was fractured. The cord was caught between the last dorsal and the first lumbar as between the blades of a pair of scissors. It was not completely crushed, as the dislocation was not extensive enough. It was impossible at the operation to reduce the dislocation, so the spinous processes and the laminæ of the last three dorsal vertebræ were removed. This relieved pressure on the cord. The patient died, however, from pneumonia a week later without any improvement in the spinal symptoms. A post-mortem examination showed the wound in an excellent condition, with the cord softer than at the time of operation, and solidification of the whole lower lobe of the right lung, and a part of the middle lobe. In the other case operation was undertaken about a month after fracture of the eleventh and twelfth dorsal vertebræ in a laborer, nineteen years of age. The cord was almost completely gone, there being a few fibers remaining from its anterior portion. The laminæ had been fractured and driven into the canal. One of the articular processes had also been driven into the canal. These were removed, and the wound closed, leaving a small catgut drain. There was no decided improvement in his condition for six weeks after the operation. At this time he urinated voluntarily; two weeks later there was noticeable improvement in both sensation and motion in the thighs. This improvement continued until the present, about three years after operation. His thighs were practically normal as to motion and sensation. Bladder and rectum acted naturally, and his general health was excellent. He could stand with support and walk by having a strong

support on each side. His legs and feet were still paralyzed, both as to motion and sensation. At present patient weighed nearly two hundred pounds, and was quite comfortable, except for occasional pains in his legs.

Immediate Removal of Neoplasms.—Dr. MAURICE H. RICHARDSON of Boston, Mass., considered chiefly neoplasms of the breast and of the female pelvis in his paper on this subject. The reasons which justified the adoption of the title rule in these regions would apply with certain exceptions to all parts of the body. These reasons, all of which were illustrated by specific cases, in the author's own experience, were as follows:

1. The uncertainty of the diagnosis, even on the part of the most experienced and the most skilful, made palliative treatment hazardous, especially in the doubtful cases. Several instances were given in which the patient was not operated upon because the tumor was supposed to be benign when, in reality, it was malignant. The error cost the patient the favorable moment for operation. The impossibility of accurate diagnosis in even the most accessible regions of the body was emphasized. Breast tumors apparently benign had proved malignant. Breast tumors benign throughout their principal areas showed minute foci of malignancy. Breast tumors clearly benign had after many years developed a fatal malignancy. So in abdominal tumors, especially the pelvic tumors in women, the difficulties of diagnosis made the apparently benign cases, especially dangerous. Many instances were given illustrating the difficulties of diagnosis and the necessity for exploration in even the most favorable cases of presumably benign growths.

2. The dangers of benign tumors becoming in time malignant was emphasized and illustrated by not a few cases in which after years of slow and harmless growth a tumor had suddenly developed evidence of malignancy. Tumors of the breast, of the gall-bladder, the stomach, the uterus, the ovary, and of other regions had, by an acquired malignancy, convinced the speaker that the only safe rule of treatment was in all cases thorough extirpation of the tumor as early as possible.

3. The wisdom of exploration in certain apparently hopeless tumors was illustrated by cases in which a benign and easily remediable condition was found, and in which impending death was averted by a safe operation. In this class were infiltrating tumors of the abdominal wall supposed to be hopelessly malignant, but which proved to be tuberculosis of the muscle, aponeurosis; epigastric tumors, apparently cancerous, found to be pancreatic cysts, actinomycosis, chronic pancreatis, and the like. Pelvic tumors supposed to be malignant and inoperable were proved to be old tubal inflammations, fibroids, ovarian cysts, and the like.

4. The essential malignancy of certain areas in the malignancy-inviting nature of certain regions, especially the breast and the ovaries, was especially emphasized. In these regions the tendency of tumors to become malignant made the application of this rule practically imperative. Ovarian tumors, even when apparently benign, were shown to have especially dangerous tendencies to malignant degeneration.

5. In pelvic tumors especially, the benign often masked the malignant. Cases were reported to illustrate the obscuration of a uterine sarcoma by an overlying fibroid. In two recent cases cancer of the ovary was found concealed by an enormous fibroid, and in a third there was found an annular stricture of the sigmoid flexure.

The rule of universal extirpation had numerous exceptions. It should not apply to superficial tumors, clearly benign, which could not be removed without great disfigurement; cheloids that could not be removed without leaving a broad scar, unless they showed a tendency to ulceration and malignancy; all other benign tumors, which caused needless suffering, disability, and disfigurement, whenever their removal was dangerous, or whenever the patient's general condition was unfavorable; and tumors of all kinds in which the dangers and sufferings of removal outweighed the dangers and sufferings of the tumors themselves.

Dr. HENRY T. BYFORD of Chicago, Ill., said he belonged to the Chicago Academy of Medicine, whose motto was, "When you see a head, hit it." He thought this would fittingly apply to the removal of tumors as soon as they were seen. A year and a half ago he was called upon to diagnose a tumor in the pelvis about the size of the end of one's thumb, which was situated between the bladder and uterus. The attending physician said that this tumor did not amount to much, and argued against operation. The woman subsequently became pregnant, miscarried at the fifth month, the tumor at this time having attained the size of an egg. He thought it would continue to grow unless removed. No matter whether a tumor was going to become malignant or not, it was a foreign body and should be removed as soon as possible.

Dr. W. P. NICOLSON of Atlanta said early operation, when safe, was to be commended in every case. He related a case of sarcoma of the mesentery in which he had operated, with recovery of the patient. He also narrated a case in which a sarcoma sprang from back of the rectus muscle and infiltrated the whole pelvis. The tumor was removed, with recovery of the patient.

Dr. W. B. COLEY of New York stated that three years ago a patient came to him with a bad cancer of the breast. She had been under the observation of an eminent surgeon, who had been watching the tumor for a year at intervals, telling her not to have anything done until he thought she needed it. The tumor was finally pronounced cancer by this surgeon, but the patient consulted Dr. Coley with a view to having an operation performed. Careful examination disclosed all the characteristics of advanced cancer. An operation was done, but the disease returned within one year, from which the patient died. He thought these growths should be removed without waiting to determine whether they were malignant or not.

Dr. W. P. CARR said that one of the first tumors he had ever removed was a cancer of the breast in a girl of nineteen. He had no idea it was cancer at the time of its removal, but sections proved it to be such. This prompted him to examine all tumors, particularly those of the breast, and he was surprised to find that a great many of the tumors of the breast which he supposed to have been adenoma proved, upon microscopical examination, to be carcinoma. He thought if surgeons made it a routine practice to examine microscopically all the small benign tumors they removed, they would find many of them to be malignant.

Dr. J. M. BALDY of Philadelphia said the more experience he had, and the older he became, the more he was convinced that the truly honest man would admit his inability to diagnose accurately many cases of tumors. He supported the essayist in saying that these neoplasms ought to be removed, no matter where they occurred. There were some tumors of the breast that were not malignant. He had removed a number of them, but he thought the vast majority were malignant. In the past year he had reoperated twice on cases of cancer that had been subjected to *x*-ray treatment, and in one he had operated a third time for the return of the disease after *x*-ray treatment, although the physician who had used the *x*-ray had said the patients were doing satisfactorily.

Dr. J. SHELTON HORSLEY mentioned a case of cancer of the breast that was operated on. There was local recurrence, and the patient was treated by the *x*-ray. After two weeks' treatment with the *x*-ray the woman began to sink rapidly and soon died. Post-mortem examination disclosed extensive metastases in the brain, liver, kidneys, ovaries, heart, etc. The *x*-ray had no beneficial influence on this case.

Intestinal Cancer.—Dr. J. G. SHERRILL of Louisville, Ky., in a paper on this subject, stated that cancer of the intestine, while rare, was more frequent than physicians were led to believe; that sarcoma was much less frequent than carcinoma, and selected especially the small intestine, while carcinoma most often attacked the large bowel. The appendix was the seat of both carcinoma and sarcoma, although occurring quite infrequently. The literature showed that men suffered from both forms oftener than women. Adenocarcinoma was the type most frequently seen, while the round-celled sarcoma or the lymphosarcoma occurred oftenest. The author reported two cases of cancer of the intestines. He said that the treatment was to be largely determined by the extent of the involvement. Resection of the intestine and extirpation of the growth offered the patient the only hope of a permanent cure, and this chance, though slight, should be given the patient whenever practicable, as early in the course of the disease as possible. Any of the classic methods might be employed.

Amputation of the Hip-joint for Sarcoma.—Dr. WM. B. COLEY of New York read a paper on this subject. He said that, in the cases forming the basis of the study, the tumor originated in the bone or periosteum of femur in five cases, and in the soft parts in two. The age of the patients ranged between six and fifty-six years. In six cases Wyeth's pins were used, but in the seventh case the growth extended above Poupart's ligament, pins could not be used, and the external iliac artery was first tied. All of the patients made a good recovery from the operation; yet only one patient survived operation long enough to be called a cure. This was a sarcoma of the thigh, in which the mixed toxins of erysipelas and bacillus prodigiosus were used for two months before amputation. In one recent case the patient was still alive without recurrence; in all the other cases death occurred from local or general recurrence in from four months to two years after amputation. Of four other cases of sarcoma of the femur and thigh, treated by high amputation, just below the trochanter, two patients died at the end of four months; one died at the end of two and a quarter years, and a third had recurrence in the gluteal region, which disappeared under the mixed toxin treatment, and the patient was alive at present without recurrence, six years afterward. The extraordinary malignancy of sarcoma of the femur was shown by the very small number of patients known to have survived for more than three years after amputation. Butlin was able to find but one case in sixty-eight treated by high amputation or hip-joint amputation. Wyeth in 1901 collected 131 cases treated by hip-joint amputation with ten alive more than three years. Dr. Coley stated that he had personally known of but six cases. In one of these cases (Dr. Bull's), operated upon sixteen years ago, a severe infection occurred in the wound, probably streptococcus, and the patient was well six years later. In another case (Dr. Gerster's) the disease was so extensive and so high up that amputation was considered impossible, and the patient was treated with the mixed toxins of erysipelas and bacillus prodigiosus for several months. The tumor disappeared, and the patient was shown at the New York Surgical Society a year ago in perfect health, more than four years after treatment. The better results following amputation in the pre-antiseptic days the writer attributed to the infection that frequently occurred in the earlier period. This fact, together with the results referred to, in which the erysipelas toxins were used, he believed sufficient reasons for advocating a systematic use of the toxins after primary amputation as a prophylactic against recurrence. He would not advise such treatment prior to amputation in sarcoma of the femur, on account of the great liability to early metastases, though in a case of sarcoma of the tibia he had been able to save the leg, and the patient was now well seven years afterward. The method of treatment advocated by Mikulicz, namely, resection of the femur, Coley did not think should be adopted as a substitute for amputation. While it was true a fairly useful limb might be obtained by resection, there were no cases treated by this method that had been observed for longer than a year, hence nothing could be said as to permanent cure. The *x*-ray, Coley believed, should never be used unless the patient absolutely refused amputation. One such case he had treated two years ago (round-celled sarcoma of femur); the tumor apparently entirely disappeared in the femur, but ten months later a large metastatic tumor appeared in the pectoral region, which was partially removed by operation. A little later another very large tumor appeared in the lumbar and iliac regions. Under long-continued treatment with the mixed toxins plus the *x*-ray, the tumors disappeared, and the patient was alive and well to-day, though by no means regarded as cured.

Diagnosis and Treatment of Gallstones.—Dr. MACK ROGERS of Birmingham, Ala., read a paper on this subject. After referring to the differential diagnosis, he spoke of the operation for the removal of stones from the gall-bladder, saying that when there were no adhesions it was a comparatively easy one, but when the stone was located in the common duct, or extensive adhesions existed, or both, the surgeon had a very difficult condition to deal with. In the hands of competent, experienced men he regarded this operation as one of the safest in the abdominal cavity. The mortality in all cases averaged only about 3 per cent.

Surgery of Urinary Tuberculosis in Women.—Dr. GUY L. HUNNER of Baltimore, Md., reported thirty-five cases occurring in the services of Dr. Howard A. Kelly and his associates in Baltimore. These patients were all women with an average age at the onset of symptoms of twenty-eight years. The disease was unilateral in 31 of the cases, and it was probably primary in the kidney, as regards the urinary system, in 30 or more of the cases; 31 cases had bladder symptoms at some time in the course of the disease, although only 18 cases had bladder lesions at the time of operation; 11 of these 18 cases still had some bladder symptoms, and 5 were known to have bladder lesions, although 9 of the 11 had had systematic bladder treatment. Tuberculosis of the bladder did not heal with the ordinary methods of treatment, and if the disease persisted a year and did not occupy more than half of the bladder, it should be excised. Of 22 ureters examined microscopically, 17 showed tuberculosis, while 5 were chronically inflamed. If a tuberculous ureter remained either in part or *in toto*, the wound usually remained opened at least two years, while the removal of the ureter with the kidney resulted in rapid closure of the wounds. Five patients died—three after six and eleven weeks, and two years respectively, from involvement of the other kidney, and two, in fifteen and six days, because of the operation. Sixty-six per cent. of the patients were enjoying fairly good or excellent health.

Spurious Dysmenorrhœa.—Dr. HENRY T. BYFORD of Chicago read a paper with this title in which he made a plea for a more rational treatment. After naming twenty-five varieties that were mentioned in the textbooks, the author called attention to their disappearance therefrom. Many supposed cases were spurious in character. These had been perpetuated by the physician and cured by the quack. The absurdity of the nasal cure was emphasized and the cures referred to as spurious. Instances of menstruation in the male were quoted. The trend of the paper was to condemn writers for bringing the symptom into the foreground when it should be kept in the background, and for wasting their own time and that of their readers in ridiculous refinements and speculations.

Memorial Address on Dr. W. E. B. Davis.—Dr. RICHARD DOUGLAS of Nashville, Tenn., spoke eloquently and impressively of the work that had been accomplished by

Dr. Davis, and pointed out in a masterly manner the distinguishing characteristics of the deceased.

Diagnosis and Treatment of Congenital Misplacement of the Hip in Infancy.—Dr. ALBERT H. FREIBERG of Cincinnati, O., had been able to ascertain that in several cases children with congenital misplacement of the hip had been late in walking. It was a common experience in mild grades of rachitis that children were late in walking. The usual age of sixteen months was passed by and the rachitic child not only failed to walk, but was usually also unwilling to stand. He had been able to ascertain in several cases and to observe in one that children with congenital luxation stood readily at the usual age for walking, and especially if allowed to support themselves by holding on to some object. It was only when independent effort at ambulation was urged that the child showed its timidity and refused to make the attempt as a normal child would. This period, of course, was gone through by every normal child, but in some cases its long continuance might be attributed to congenital luxation. The length of this period in luxation cases varied greatly, but in every case was finally determined by the child's learning to walk with more or less limping, at which time the diagnosis was usuailly made and was of no further interest in this connection. In some few instances mothers observed these things, and possibly also that the apparent breadth of pelvis and perineum was unusually great. It was therefore urged that in the presence of any of these signs which had been referred to, attention be paid to the possibility of congenital luxation, and that in the event of any doubt, the *x*-ray be resorted to as a final means of precision. Experience had abundantly shown the feasibility of operative procedure after the age of one year, and that the results amply justified the great additional care which was necessary to prevent the dressings from becoming soiled in so young a patient.

(To be Continued.)

THE SOCIETY OF MEDICAL JURISPRUDENCE.

One Hundred and Seventy-seventh Regular Meeting, Held on Monday, December 14, 1903.

MR. THEODORE SUTRO, PRESIDENT, IN THE CHAIR.

A Plea for Justice to the Consumptive.—Dr. S. A. KNOPF read this paper (see page 1).

Mr. CHARLES P. BLANEY opened the discussion and said that the people in the majority of instances were the owners of the land throughout the State, and that it was not the privilege of any one class of citizens, where the public funds and public health were concerned, to retain ownership of land in any part of the State. He said that Dr. Knopf had shown that the law as it stood on the statute books prior to 1903 was sufficient to protect this class of citizens against such dangers, even if they existed, and especially against the spread of pulmonary tuberculosis. The law as it stood previously allowed cities of over 1,000,000 inhabitants in this State, whenever they desired to regulate sanatoria in various townships, to appeal to the State Board of Health, and if the State Board of Health decided that it was advisable to build such sanatoria in the State, in such a township or village, then it was required that certain properties should be condemned and sanatoria built thereon. He said that prior to the Goodsell-Bedell law sanatoria were established in this State and in the Adirondacks, and people who were afflicted with this disease and who were a menace to the inhabitants of this State would go there and perhaps be cured and so avoid the great expense of going West and perhaps dying there away from home and friends. He believed that almost every advantage given the consumptive had been eliminated by the present law. Take, for instance, large regions in Orange County where it would be possible to use acres and acres of land to build private hospitals for the consumptive, the town authorities, being influenced by men of wealth or those who desired no disfigurement to their properties and who would exert a little pressure upon the town authorities, would not permit such hospitals to be built, and therefore the benefits which might have been derived would be entirely cut off merely from the fact that certain private individuals thought that such institutions might be a disfigurement to the property. Such hospitals he said were not dangerous; it was well known that consumption would not be carried the distances people believed it would, and he believed it was right that the people of the State of New York should have such sanatoria established, and he thought it was the duty of the people residing in the City of New York to see that the law as it now stood, was repealed, and that the law as it stood prior to 1903 be placed on the statute books.

Mr. CHARLES M. DEMOND said that, from a legal standpoint, no law should be passed and no regulation should be promulgated unless there was some evil to be remedied. Laws were not enacted by the United States Government unless there were some crying evils to be remedied. He said it might be that the regulation to exclude emigrants was too broad, and it might be too that if the consumption was not particularly communicable, such regulation as proposed might be too stringent. He thought the Goodsell-Bedell law, as it now stood, increased consumption in the tenements. It was evident that consumption was communicable and probably in direct ratio to the crowded condition of the tenements. He asked what the morality of the consumptive had to do with the Goodsell-Bedell law? He said he believed in the regulation of all institutions which pretended to cure humanity. There was a time in England when insane asylums were run by private individuals and it was not until some author exposed them that there was a revolution. He said it was desired by many to build sanatoria giving unlimited license to all the diseases that flesh was heir to. The law must be regulated, otherwise we have merely license and not law. Unfortunately he said there was a danger, but he asked what morality had to do with it? It was immaterial whether or not a man was selfish. The real question was this: "Is the presence of sanatoria a good thing for the people owning the land?" He believed in local self-government, and that was what the Goodsell-Bedell law gave, for it stated that you could have all the sanatoria you wished in any town provided you got the consent of the Supervisors or Board of Health. To him it seemed as if the law was a very proper and sanitary one and the people were not deprived of the right to established sanatoria as before; he did not see how the law of 1890 was repealed by this Goodsell-Bedell law. The question with him was, can they, as a society, take such a stand as proposed by Dr. Knopf? Was it logical? Was this a good law? Were they going to encourage careful inspection of all governmental and private institutions? He believed in it, for there was nothing so dangerous as an irresponsible private institution. He believed the white light of scrutiny should go through every public and private institution for the cure of the people which were *quasi*-governmental. We should know how such institutions were operated, how much was paid them, whether they were enterprises for gain or for the good of the community, all this should be given the people. He did not believe the society should pass the resolution as proposed. Consumption might be classed with smallpox or yellow fever, and if he knew he could get either of them he said he wanted to keep far away from them. Coming from the West he had seen people going to Arizona and Colorado to be cured of consumption and once one of these patients died on the train and he was told by one of the doctors present that he was breathing some of the dried sputum. He did not care to meet with such conditions. What was said regarding the highest authorities on the question of morality he said was irrelevant and could not affect the Goodsell-Bedell bill. He believed in a resolution that the Charity and Health Commissioners establish health sanatoria; that it should be done under the law; that it should be done

right and should not injure anybody. He said he was opposed to having the society state in its wisdom that it knew more than the United States Government and he believed that it was creating a hardship if the law as proposed was signed. If one wished to establish such sanatoria he asked why the Supervisors could not be approached and persuaded to allow it done.

Dr. H. M. KING of Liberty, N. Y., said that consumption was not to be feared at all in the same sense that smallpox was, for it depended for its development upon so many factors besides the tubercle bacillus, such as the poorly-ventilated offices, the badly arranged residences of the working people and many other factors too numerous to mention. The mere fact that a consumptive was in our midst was no reason why other people should be affected, provided the consumptive be properly instructed in the care of himself. He knew of no stronger argument in this regard than that during the past year, at the Loomis Sanatorium, there were several children, children of consumptive invalids under treatment, and they were there without danger to themselves. It seemed necessary now to combat the ridiculous ostracism to which the consumptive invalid was exposed. He said the crusade against the consumptive started in the West, where a law was passed in several cities against the consumptive and he said it was absurd and unjust to deal in this way with the individual who had contracted consumption. It was Naegli who found, among autopsies performed on people who died from all kinds of diseases, that 98 per cent. of all invalids over thirty years of age had in some parts of the body evidences of tuberculosis; that only one in seven died from consumption, while one in three had pronounced lesions and four out of seven recovered from the disease with healed lesions.

Dr. H. W. BERG said he did not believe the profession at large imagined the consumptive insane or mentally unsound and that certainly the physicians of this city did not have such an opinion, and, therefore, it appeared to him that the gentleman referred to in the paper, a man practically unknown, had acted as a phantom and Dr. Knopf was attacking an adversary unworthy of his steel. He warned the society not to resolve anything as proposed by Dr. Knopf if they did not wish to make themselves ridiculous. Regarding the question of the mental state of the consumptive, it must be remembered that some of the best, wisest, and brainiest men were consumptive and, as quoted from Naegli, 98 per cent. of human beings had consumption, although often dying of other diseases. He asked if 98 per cent. of all men were insane. No human being with any regard for what he writes would say that consumptives were mentally insane. He said that so far as the Goodsell-Bedell bill, or all legislation in fact was concerned, all emanated from the doctors and not from the lawyers. He said that no president of the United States, no governor of any State, no mayor, nor any legislative body ever proposed or passed a law of any kind or description against the consumptive, without being led thereto by action of physicians. Every time action had been taken it had been backed by eminent members of the profession. He believed the laity had mistaken the terms contagious and communicable, thinking they were synonymous. By communicability one meant taking some emanation from a sick body and absorbing it into one's own. He said that consumption was not contagious but communicable. The ignorant laity think, when legislative bodies legislate against the communicability of something, that they are legislating against the contagiousness of something.

Mr. E. T. DEVINE, Secretary of Charity Organization Society, said that being neither a physician nor a jurist, he could approach the subject in an unprejudiced manner. He wished to say a word regarding the central feature of the paper and also upon the wisdom of a particular piece of legislation. It seemed to him that the doctor was speaking ironically when he stated that all the bills that got through the legislature were passed for the public good; occasionally, he said, things slipped through the legislature for other reasons, and as an example of this, he briefly referred to what had recently happened above Tuxedo Park, where a man owned a piece of land adjoining a club, and who wished to dispose of it at an exorbitant price to this club. He wanted to make it absolutely necessary that the club should purchase it and, therefore, he came to the Health Commissioner of New York City and said, "I have a piece of land well located and I am going to offer it to you free for a certain time if you will promise to use it for a camp for consumptives." The Health Department was anxious to get the land for that purpose and so closed the offer. The object of this was to make it necessary for the club to buy the land at his price. The club refused to pay, but they went to the legislature and asked them to pass a bill making it impossible to build such a camp without the consent of the township, making it necessary for them to get the consent of the township as well as that of the Board of Health. The Assembly at Albany, to their credit, vetoed this bill, but within an hour of the time they vetoed it a friend of the Governor appeared on the floor, asked them to reconsider their vote, which they did and the bill was passed. He said that was the way the Goodsell-Bedell bill was passed, and he did not think it was passed for the interest of the consumptive but in the interest of the State. This was not simply an instance of recognizing local government, for we have a requirement which stated that the State Board of Health must also give its consent for the erection of such an institution, they both have a voice in the matter, and when you add to this the consent of the township and the county authorities, he said, you must see how impossible it was to build such a camp. He said it would have been impossible for Dr. Trudeau or Dr. Loomis to have built their sanatoria if the Goodsell Bedell bill had been upon the statute books when these institutions were built. He hoped that when the opportunity presented itself the society would aid in the repeal of this measure.

Mr. WILLIAM R. A. KOEHL endorsed very heartily the views expressed by Mr. Demond, and he regretted very much this semi-political discussion in regard to the whole matter. It was regrettable that the speaker of the evening should refer to the Governor of the State as "our most distinguished Governor," for the Governor of our State did not make a bill, but he was a mere incident; the President of the United States was a mere incident to a bill. He said a man may be condemned whether he vetoes a bill or not. He was opposed to the resolution in its present form. He said he was not opposed to the consumptive and wished to help along the interests of the consumptive. He believed the matter should be laid before a committee for action, and he moved that it be referred to a Committee of Five to be appointed by the Chair and who should report back to the society at its next meeting.

(It was then further amended that the resolution be referred to the Board of Trustees for action. This was carried.)

Dr. S. A. Knopf closed the discussion and said that he only wished that Mr. Demond's statement that "all laws were good" was true. In regard to the difference which existed between consumption and smallpox he would gladly enlighten Mr. Demond by saying that the latter is a dangerous contagious disease, the former simply a communicable disease, and he illustrated the difference by saying that a well-conducted sanatorium for consumptives was the surest place for a well person *not* to contract the disease, while in the smallpox hospital, no matter how well kept, one would be sure to contract the disease unless vaccinated and revaccinated. There is no danger

in associating with a clean, conscientious consumptive, there is always danger in associating with a smallpox patient.

Mr. Demond, Dr. Knopf said, had made the statement that there was no such a thing as hardships imposed upon the consumptive. He evidently has had no experience with consumptives. To realize the hardships which are so often unjustly imposed upon the pulmonary invalids one must have been touched by the presence of consumption in one's own family or that of a near friend, and only then one will feel how greatly the consumptive deserves our sympathy.

In answer to Dr. Berg's criticism for having taken notice of an article written by a man unknown to the profession, Dr. Knopf said he thought it neither kind nor just to ignore the author of a work because he was not well enough known by the profession. Every well-known author must have been unknown at one time of his life. The fact alone that what Dr. Saxe wrote had appeared in two issues of the *New York Medical Journal* justified the consideration of the article and the author. Extracts of Dr. Saxe's article had been copied and recopied, not only in many medical, but also in quite a number of lay papers, and Dr. Knopf said that he had letters in his possession which showed the fruits of spreading such ideas. Furthermore, Dr. Saxe was not the only medical man afflicted with phthisiophobia, and when such statements were published as those promulgated by that author, or by other physicians or laymen, Dr. Knopf would always consider it his duty to protest against them.

In regard to the Goodsell-Bedell law, he could only repeat that resolutions were passed condemning it, not only by the Academy of Medicine, but also by numerous other medical societies of this city and State, besides the protests mentioned in his paper from the Charity Organization Societv and the Masonic fraternity.

As a reply to Dr. Berg's accusation that Dr. Knopf was largely responsible for the compulsory reporting of tuberculous cases in this country, he would wish to say that he had always advocated what might be called a facultative, but not a compulsory registration. The Health Board of the City of New York requests that the physician reports the name, age, sex, and residence of the tuberculous patient, and whether there are any other members in the family afflicted, and asks if the attending physician wishes that an inspector from the Health Department should visit the patient's residence. If the attending physician does not desire to have this done there will be no interference. Surely such registration did not imply any hardship to the patient, his family, or his physician, but it was a valuable aid to statistical science, it told of the whereabouts of consumptives and of the districts which were particularly invaded by tuberculosis. Nearly all medical men favored such registration, and Dr. Knopf said that he had met few who would not wish to comply willingly with such regulations.

Dr. Knopf again asked the society to aid in the repeal of the Goodsell-Bedell law, and thought it wise to consider the steps to be taken in this matter quietly in special committees made up of lawyers and physicians. To combat the private phthisiophobia, which he believed existed to a most alarming extent, he would urge the authorities to give a better example and be helpful in educating the people at large to the fact that the conscientious consumptive is as safe an individual to associate with as any well person.

Officers Elected.—*President*, Theodore Sutro; *Vice-President*, Dr. Carl Beck; *Treasurer*, D. McLean Shaw; *Recording Secretary*, John C. West; *Corresponding Secretary*, Alfred E. Ommen. *Trustees*, Drs. Edward F. Brush, Frank Furguson, E. J. Palmer, and C. A. Ramdohr; Messrs. George C. Andrews, Charles P. Blaney, Charles M. Demond, Frederick B. House, and Henry Melville.

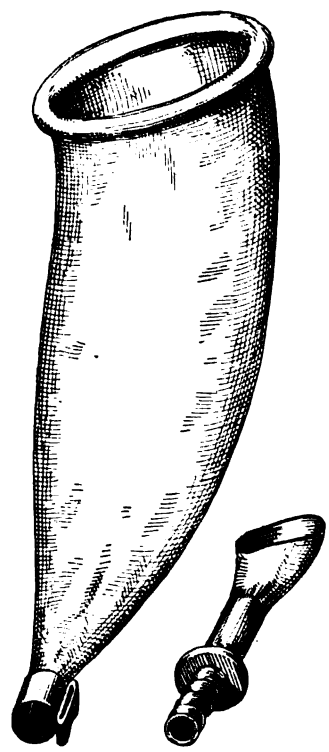
New Instruments.

A NEW FEMALE URINAL.

By FRIEDRICH GROSSE, M.D.,
NEW YORK.

Mrs. X. came under my treatment with a carcinomatous destruction of the bladder wall and vagina, causing incontinence of urine. She had two urinals of the well-known shapes, but they did not answer, being dislodged by every movement. The permanent leaking of the urinals had given rise to the worst inflammation of the skin I ever saw. The external sexual organs and neighboring regions were highly eczematous, ulcerated, and, in addition, bedsores occupied the dependent parts. The minutest shifting of the urinal exaggerated the apparently intense pains. The patient was so exhausted from lack of sleep and appetite and terrible suffering, that death seemed to be a question of only a few days.

Although the family tried to keep her dry and clean, the offensive smell was almost unbearable. Everything was done to alleviate her condition, and finally I devised an apparatus which, on being inserted into the vagina, could drain away the fluids without touching even the labia. This apparatus consisted of an annular brim of a watch spring, about one and one-half inches in diameter, covered with rubber dam, and attached to it a small bag of the same soft material, the tapered end of which was fastened to a hard-rubber piece which allowed a rubber pipe to be drawn over it, to lead off the discharges into a vessel below the bed.



The apparatus was easy to introduce, caused no complaints whatever, and worked excellently, so that the patient lay absolutely dry, and could be kept clean. Although the smell had penetrated the whole apartment, it was entirely banished. The inflamed skin soon became healed and the patient gained in strength and flesh, as far as the cancer permitted. Not long afterward I was surprised to find the sufferer out of bed, sitting in a chair, with the apparatus on. She had bound the bottle of one of her old urinals to her leg, and the pipe of the little bag connected with it. She could take it out, clean it, and introduce it herself without any difficulty.

Incident to the splendid result in this case, I tried it later with women whom I treated with ichthyol tampons, to prevent the cloths from being soiled, the tapes of the balls being put into the bag. As the amount of discharge in such cases was small, I had the end of the bag closed, and a little eye attached to it, through which, by means of a wool thread, the bag could be fastened to the thigh. All the women highly appreciated the new instrument, and one of them suggested that it would do the same service during menstruation. I followed the idea and tried it in about fifty cases, in all of which it gave satisfaction; none of the women had any

inconvenience and all preferred it to the sanitary napkin.

The diameter of the brim of the instrument varies according to the width of the vagina, and the length of the bag of the closed variety according to the quantity of fluid. In cases of incontinence of urine, the apparatus has to be used with a drainage pipe and a reservoir like the old urinals.

The insertion is done by the woman herself, introducing the ring about three inches into the vagina. A slight traction with the bag, in an angle of forty-five degrees, will bring it behind the hymenal ring, where a slight resistance will give the signal to stop, and the instrument will rest safely. A little stronger traction in different directions will remove it without difficulty.

The apparatus is superior to the common urinal, by, first, being incomparably lighter, the weight being only ten grams or so; second, adhering to the body without bandages; third, closing absolutely, provided the proper size is taken, and avoiding even moistening the labia majora. All women stated that in case of menstruation it was more comfortable than the bandages and caused no irritation whatever.

It will certainly be of great benefit in cases of permanent irrigation of the internal sexualia, in which the affluent catheter may be introduced by a hole cut into the bag, the wash will have its exit by the mentioned rubber outflow.

The instrument is inferior to the common urinal by being unavailable in the case of a virgin, and in that of incontinence of nervous or muscular origin.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Infectious Diseases, Their Etiology, Diagnosis and Treatment. By G. H. Rogers and M. S. Gabriel, M.D. 8vo, 874 pages. Illustrated. Lea Brothers & Co.

Gesammelte Abhandlungen über Zuckerbildung in der Leber. Von Prof. Dr. J. Seegen. 8vo, 492 pages. August Hirschwald, Berlin.

Months and Moods, a Fifteen-year Calendar. By Edward Curtis. Square 4to. The Grafton Press, New York.

The Purin Bodies of Foodstuffs. By I. Walker Hall, M.D. Second edition (revised), 4s. 6d. 12mo, 214 pages. Sherratt & Hughes, London. Price, 4.6.

The Principles of "Open-air Treatment of Phthisis and of Sanatorium Construction. By Arthur Ransome, M.D. 8vo, 104 pages. Smith, Elder & Co., London.

Operationen am Ohr. Von Dr. B. Heine. Mit 29 abbildungen im Text und 7 Tafeln. 8vo, 178 pages. S. Karger, Berlin. Price, M. 6.

The Worth of Words. By Dr. Ralcy Husted Bell and Dr. Wm. Colby Cooper. Third edition, 12mo. 307 pages. Hinds & Noble, New York City.

The After-treatment of Operations. By P. Lockhart Mummery, F.R.C.S. 12mo, 221 pages. Illustrated. William Wood & Company, New York. Price, muslin, $2.00 net.

Infection and Immunity with Special Reference to the Prevention of Infectious Diseases. By George M. Sternberg. 8vo, 293 pages. Illustrated. G. P. Putnam's Sons, New York.

A Manual of Bacteriology. By Herbert U. Williams, M.D. Third edition, 8vo, 351 pages. P. Blakiston's Son & Co.

Paul Guttmann's Lehrbuch der Klinischen Untersuchungs-Methoden Brust- und Unterleibs-Organe. Von Dr. Felix Klemperer. 8vo, 529 pages. August Hirschwald, Berlin.

Therapeutic Hints.

Eczema of the Eyelids.—Brocq uses locally for this condition, warm compresses of boric acid, followed by

Oxide of zinc		
Starch powder	āā	ʒii. p.
Lanolin		
Vaselin	āā	ʒiv.

M. When the inflammation has subsided the following ointment is used:

Yellow precipitate	gr. x.
Vaselin	ʒvi.

—*Medical Press.*

Corneal Ulcer in a Torpid State.—

℞	Hydrarg. oxidi flavi	gr. i.
	Atropinæ sulph.	gr. ¼.
	Vaselini	ʒi.

M. A small portion to be introduced between the lids night and morning. —De Schweinitz.

Coryza.—

℞	Powdered starch	10 parts
	Boric acid	1 part
	Bismuth subnitrate	½ of each
	Powdered quinine	½ part

S. Use as snuff.

—Hirtz in the *Clinical Review.*

Ethyl Anæsthesia.—Chloride of ethyl anæsthesia is easy and rapid and free from discomforts and danger. The fluid should be poured upon a mask or compress, a drachm or so at a time, and inhaled deeply. If the dose is repeated at intervals of five minutes, seldom more than an ounce is required. Anæsthesia results rapidly in about three minutes, and is indicated by muscular relaxation, sometimes by a dilatation of the pupils and loss of corneal reflex. There is no period of initial excitement, depression of heart, or respiration. There is seldom nausea or other ill effects. It is ill adapted to lung operations, but may be used to advantage as a preliminary to ether chloroform or ether. —Vanverts.

The Prevention of Chloroform Accidents.—Felchenfeld has made some recent additions to his suggestion that tincture of strophantus should be given in frequent five-drop doses for two or three days prior to chloroform anæsthesia, in order to strengthen the heart action. He has recently insisted on the importance of frequent examinations of the heart before the administration of chloroform, even though the organ is found sound at the primary examination. In the case of a strong and robust man, preliminary strengthening of the heart is quite unnecessary. In case of nervous irritability of the heart indicated by dulness of cardiac sounds, by a somewhat diffused and indistinct apex beat, and by a small and very rapid pulse, the author would give small doses, not more than 5 drops, of tincture of strophantus and tincture of digitalis three times daily, for some days before the operation. The good effects of this treatment are shown by a reduced pulse rate, less mental depression, and anxiety, improved appetite and good sleep. The pulse rate, it is stated, should be reduced to 80, at the highest, before a subject of cardiac irritability can be chloroformed without risk. In a second group of cases, in which there is a distinct evidence of muscular degeneration varying from slight forms of muscular weakness to grave myocarditis, the author would endeavor to fortify the flagging heart and to improve the rapid and irregular pulse; and with such object in view would substitute for the first described method of treatment warm baths, carbonic acid baths, and injection of strychnine; the administration of digitalis being continued in the form of infusion. In cases of this kind, ether should be used as the anæsthetic in preference to chloroform. The most difficult cases to deal with are those of hypertrophy of the cardiac muscles, which need careful prophylactic treatment, and in which the action of the anæsthetic should be assisted by an injection of morphine at the seat of operation.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 28, 1903:

	Cases.	Deaths.
Measles	438	6
Diphtheria and croup	379	50
Scarlet fever	277	30
Smallpox	1	...
Varicella	116	...
Tuberculosis	217	161
Typhoid fever	61	14
Cerebrospinal meningitis	...	4

Hypophosphites of Calcium, Sodium, and Potassium in the Prevention and Treatment of Abscess.—Sinclair Tousey presents the following formula as an improvement upon some of the more familiar ones in the prophylaxis and treatment of suppurative conditions, notably of the cutaneous and lymphatic organs produced rather by the state of the system than by infection. The combination which has been found most effective is ℞ calcii hypophos. gr. v; sodii hypophos. gr. ii, pot. hypophos. gr. ii. This is one dose and may be prescribed in syrup or in capsules. The latter may conveniently contain half a dose apiece, two being taken at one time, and followed by half a glass of cold water. The author has not met with any disagreeable results from the use of this formula, and has found it most useful in cases which there is simply a swelling of the subcutaneous tissue presenting well-marked fluctuation, without redness or pain. He has treated such swellings in the perineum, the axilla and about the neck and caused their entire disappearance, though at the commencement of treatment there was unmistakably a drachm of fluid pus present.—*Annals of Gynecology and Pediatry.*

The Relation of Hysteria to the Female Genitals.—Voss points out that the tendency of modern gynecologists is to modify the older view that hysteria was to a large extent founded on abnormalities of the pelvic organs. It is more particularly the neurologists, whose observations show that hysteria and the female genital system do not possess essential causative inter-relationship, while on the other hand gynecologists also have found that many conditions formerly believed to underly nervous disturbances have nothing in common with them, and that symptoms supposed to have a sexual etiology were of purely neurotic nature. The author's observations on ninety-six patients, showing hysterical symptoms, revealed sexual abnormalities in only nine. Of these, two were congenital malformations, and in only two of the entire number could any connection with the nervous condition be traced. The author believes that hysteria does not arise from affections of the female genitals oftener than from other morbid conditions. There are, however, nervous symptoms dependent on the genitals which simulate hysteria, such as reflex neuritis, neuralgia of the pelvic plexus and sciatic nerve, sacralgia, etc., but they are of direct and not of reflex origin. Most of the neuroses coming under the gynecologist's care are not true hysterias, and rarely offer the typical symptoms of disturbances of sensibility, pressure points, convulsive seizures, etc., but the diagnosis must be made chiefly on the history and the discrepancy between the subjective symptoms and the slight objective lesion. When any serious condition does not appear likely it is better in such cases to refrain from internal examination. The possible consequences of even slight operative procedures must not be underestimated, as even the narcosis alone may be of moment in those of neurotic predisposition.—*Monatsschrift für Geburtshülfe und Gynäkologie.*

Typhoid Spine.—J. W. Cannon describes his own case of typhoid fever. Ten days after a relapse of his case, in turning over in bed a sharp pain was suddenly experienced in the lumbar region of the spine. For more than two months it was impossible for him to assume a sitting posture, so great was the pain induced. In turning over in bed he had to be very careful and use every precaution to keep the shoulders and hips moving at the same time to prevent any rotary motion of the spine. It is evident that the initial attack was caused by strain in turning over in bed. The pain was not unlike a sudden "crick," so often described by men engaged in lifting heavy weights. The point of injury was felt to be about the fourth and fifth lumbar articulation whence the acute spasmodic pains radiated. The author feels sure that there was periostitis of the anterior and lateral parts of the vertebræ, the inflammation extending to the ligaments, deep fascia and muscular attachments—neuritis, due to thickening of the periosteum, and injury to the nerves as they escape from the intervertebral foramen. Morphine, chloral, and bromides were of no practical benefit, nor were heat, massage, and electricity. Rest is the best treatment, and the more strictly adhered to the better. Recovery has at last been established with the exception of some weakness of the spine and slight tenderness.—*Medical Herald.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended December 19, 1903:

ETIOLOGY OF RHEUMATISM: OBSCURITY, INSIDIOUSNESS, PREVENTION, AND MANAGEMENT IN CHILDHOOD.

BY JOSEPH E. WINTERS, M.D.,
NEW YORK.
PROFESSOR OF THE DISEASES OF CHILDREN, CORNELL UNIVERSITY MEDICAL COLLEGE.

RHEUMATISM is caused by non-neutralized acid-products of proteid metabolism. It is cured by basic constituents of food.

Salicylate of soda from oil of wintergreen is a specific for acute active manifestations; *cure* is by neutralization in tissue fluids and cells of acids of proteid metabolism by bases abundant in certain articles of diet.

Every disease in its most pronounced typical form, has one unequivocal, absolutely diagnostic, pathognomonic symptom. In rheumatism this is profuse, sour-smelling, acid perspiration. The normally alkaline saliva becomes acid, the urine is hyperacid, the fæces become acid. This condition belongs exclusively to rheumatism.

Vital processes of tissue cells are dependent upon alkaline tissue fluids.

In the normal state, acids of metabolism are *immediately* neutralized by basis held in organic combination with the proteid, and by alkali-carbonates from oxidation of vegetable acids.

In pathological conditions the first of the reserve alkalies to be drawn upon for neutralization of acids, are those of the blood. Reduction in alkalescence of blood, causes disintegration of red blood cells.

Sodium and potassium compounds are the chief elements in maintaining alkalescence of the blood. In aggravated rheumatic states, sodium carbonate of the plasma is decomposed, carbonic acid set free. Sodium transports carbonic acid to the lungs, where it is eliminated. Accumulation of carbonic acid in the blood, and in all fluids and cells of the body, shuts off oxidation.

Menacing symptoms in rheumatism are due to rapid large withdrawal from blood of the basic element, sodium; fatal reduction in alkalescence of blood; liberation of carbonic acid; arrest of detoxicating oxidative processes.

With prolonged gradual disarrangement, as in unremitting chronic states, the most resistant fixed alkalies of bone tissue are attacked; the osseous frame-work undermined; osteo- or rheumatoid arthritis.

This explains rheumatism from muscular and articular soreness following unusual exercise, with sudden checking of elimination, to rheumatic anæmia, and rheumatic hyperpyrexia. It also makes it clear why there is no line of separation between cases classified as subacute and acute; between chronic and subacute; from acute to hyperpyrexia. They are varying degrees of the same chemical disorder, alternating, blending indiscernibly.

Cases in which hyperpyrexia supervenes, are identical with the usual acute cases, at the outset.

Neglected, acute rheumatism may evidence no moderation for weeks; yet after four or six weeks of unrelinquished severity, it is as amenable to enlightened treatment as it would have been on the first day. With the application of unchanging chemical laws at any time in its course, counteraction is at once prompt and complete. Decisive, irrefragable attestation of chemical etiology.

Uncomplicated rheumatism, irrespective of duration or severity, never ends in suppuration. This extraordinary feature is likewise explained by the chemical nature of the complaint. Numerous recrudescences at varying intervals for years, constituting a part of the life history of the patient, can be solved only by recognizing its issuing from disordered metabolism.

Deficiency of basic constituents and of vegetable acids in food; excess of animal proteid, particularly nuclein; imperfect oxidation; defective elimination, are etiological factors of rheumatism.

Alcohol is a potent factor, by its action on the liver, where much important metabolism takes place; by interference with oxidation; by causing retention of poisonous waste products in all tissues and fluids of the body. The effect of alcohol is irremediable by any management, the cause abiding. Seldom does a patient keep faith with his physician regarding this important factor.

Foods rich in basic constituents and vegetable acids, organically combined with vegetable proteid, with a minimum of animal proteid; proper oxidation and elimination, *cure* and *prevent* rheumatism.

An alkaline base in organic combination, is stored with the proteid with which it is absorbed and assimilated, only to be excreted after metabolic decomposition, thus ensuring the presence of these bases at the spot where acids of metabolism are set free. If absent or deficient, the acids satisfy their chemical affinity by union with those bases which are constituents of living tissue.

Mineral water, drugs, alkaline solutions, may render the urine neutral or alkaline, without in the least influencing or neutralizing tissue fluids—they never reach them, therefore they never cure—only relieve acute phenomena.

For healthful metabolism, and neutralization of acid-products, there must be definite, constant proportions of potassium and sodium compounds.

To reach the tissues and tissue fluids, they must be in organic combination as produced by nature. Potassium is chiefly taken in with food; sodium compounds are largely formed by oxidation of vegetable acids. Vegetable food contains three to four times as much potassium as animal food. Cereals, potatoes, bread, all important vegetable articles of diet, are rich in potassium, and are essentials of the diet with rheumatic predisposition.* Salts of vegetable acids, by oxidation in the body, form alkali-carbonates. Vegetable acids, therefore, are equally

*It is most essential that potatoes, however served, should be cooked in their jackets; for the reason that the outer rind, just under the thin skin, is the richest in potash, and constitutes a chief supply of these salts to the body. This portion is sacrificed in peeling. As far as practicable, vegetables should be steamed instead of boiled, as boiling dissolves out the potash salts. Fruit should be eaten raw. When cooked the chemical union of salts of vegetable acids is destroyed.

indispensable with potassium, with the rheumatic disposition. All vegetables contain vegetable acids, but fruits are especially rich in them.

Unerring chemical laws plainly order and prescribe rich potassium-containing foods, and fruits charged with vegetable acids for the rheumatic diathesis. Experience exemplifies the soundness, the infallibility of chemical teaching.

Withdrawal of these foods, so commonly practised, is an inexplicable and an inscrutable physiological blunder.

Rheumatism is preventable, absolutely, indubitably.

This is vital in childhood.

Rheumatic tonsillitis, rheumatic torticollis, rheumatic inflammation of a single tendon, hamstring, dorsum of foot, hand, etc., is notably liable to have a concomitant, insidious endocarditis in operation; frequently an incurable valvular lesion has origin in a phenomenon seemingly so trivial.

A minor manifestation is often fraught with momentous import.

Etiology foreshows heart disease of rheumatism may be forestalled.

In a young child, pronounced unmistakable rheumatism is exceptional, while obscure, disguised forms abound.

Masked, equivocal, misleading expressions, typify the rheumatism of childhood, and are the basis of nearly every case of heart disease in children.

A child has evening temperature; a night's rest and the warmth of the bed bring morning remission. For many successive nights and days these periods are reënacted. Influenza, malaria, typhoid fever, remittent fever, catarrhal fever, mucous fever, indigestion, one, or all in turn, are diagnosticated. Purpuric spots; an exudative urticaria, a scarcely noticeable stiffness of a muscle; later a persistent anæmia, and, perhaps, a chorea and a valvular murmur, disclose the true nature of the ailment.

Minute examination would have revealed a sensitive joint, muscle, or tendon—perchance an endocarditis is betrayed. In a child with temperature, diagnosis is not complete until rheumatism has been excluded absolutely, not only by elimination of above signs, but by securing the effect of a clean tongue, and a milk diet.

Pleurisy with effusion is often rheumatic, and pneumonia occasionally is so, but neither is believed to be until a valvular murmur is audible.

Recurrent causeless vomiting* is an unfailing portent of lurking rheumatism.

Early, prompt detection and labeling of defaced types, makes it feasible to avert the discrediting, deprecable, deadly valvular defect.

To achieve this, the same trained skill, and the patient, attentive care are called for, which the archæologist brings to bear in deciphering an effaced inscription on an ancient tablet.

Anæmia with endocarditis may be the only features. With no outward mark or token, the organism may be profoundly, irreparably afflicted. Prevention is paramount in a child.

In adults, endocarditis is not concomitant to minor rheumatic phases. How interpret this modification with cessation of growth? Physiology of childhood illuminates.

In an adult the voluntary muscles constitute about 43 per cent. of the total body-weight; in a young child relatively about one-half this proportion. The incidence of rheumatism in childhood is most strongly marked when the muscles are growing rapidly, and when there is greatest muscular activity. The constituents of growth are proteid and mineral salts. *Phosphate of potash is the predominating salt in muscle. To provide for muscle-growth, alone, makes enormous demand for potash.*

Metabolism of growing structures, is from 2½ to 6$\frac{8}{10}$ times greater than it is in parts already formed. Rapid metabolism of growing muscles, with correspondingly large acid-products, necessitates an equivalent of neutralizing potash. *Muscle-growth in a child, to be normal and healthful, must be chiefly of that proteid which carries with it the fullest ratio of potassium salts, i.e. vegetable proteid.* The enduring tissue of the hardy farm lad, is preëminently the product of vegetable proteid with abundant minerals in organic combination.

At the point of contact of the lunula of the mitral valve with systole, the fibrous portion is reflected, forming a fibrous fold or band. At this fold there is localized exaggerated cell proliferation, a concurrence of growth of the leaflets, with coincident intensification of vulnerability. Moreover, there is forcible mechanical impact with each and every systole.

Owing to these two physiological conditions, every acute endocardial inflammation in a child has its inception on the auricular surface of the mitral valve, at the fibrous fold, at point of contact with systole.

The large appropriation of potash by the growing muscles; the exuberance of acid-products of the muscle-laboring child, make the balance between supply and demand of minerals close and easily lost. With every overplus of acid-products, growing mitral leaflets of heightened susceptibility, and of incessant mechanical stimulation, feel first and greatest the acid irritant.

Inflammation once set up in a growing structure, advances with perplexing virulence.

To safeguard a child's heart absolutely, he must be rheumatic-free. Inexorable physiological and chemical laws preclude this, without an abundance of potassium-containing food—cereals, vegetables, fruit.

To meet other physiological requirements, animal food is requisite, but it should not exceed the system's daily needs, as it overstimulates metabolism, and thereby prevents tissue-building.

MANAGEMENT

For the control of active rheumatic manifestations, there are two leading and chief factors—the state of the digestive organs, and the diet.

With a coated tongue, give calomel, followed by rhubarb and soda; the latter to be persisted in as long as the tongue is furred. The dose of rhubarb is proportionate to its effect on the bowel; soda should be in twenty-grain doses three times a day, before nourishment.

Milk should be the sole food as long as evident symptoms remain.

The proteid of milk contains no nuclein, and yields no uric acid. The urine becomes uric acid free on milk diet. Milk contains an abundance of phosphate of potash—muscle-salt (See above). Citric acid, a valuable anti-rheumatic, is present in considerable amount.

The first extension of the diet should be the addition of a strained cereal to milk.

Mention of cereal within hearing of the patient is unfortunate and injudicious. The rheumatic child invariably has an abhorrence of cereals. This constitutional loathing of the child's natural food is traceable to faulty feeding. Savory broths, soups, beef juice, excess of meat, etc., create a repugnance to the vitally indispensable cereals and vegetables. *Animal broths are totally destitute of food properties.* This is ancient, recent, and unalterable physiology.

*Absurdly denominated "cyclic vomiting." "Automobile vomiting" would be as fitting; no more grotesque; equally scientific.

Nevertheless, physicians wittingly and knowingly recommend them for children, where the first requisite of all food is its building, or tissue-forming value. There is a vast amount of obscure ill-health in children from heedless use of these foodless preparations.

When animal food is to be added to the diet it should be in the form of meat, not broths or beef juice. The contained extractives of broths and beef juice, by overstimulating metabolism, aggravate rheumatic anæmia and every rheumatic tendency.

Cereals must be eaten without sugar.

Sweets and animal broths in children, and alcohol and sweets in adults, are the bane of the rheumatic patient, and constantly discredit the physician by thwarting all treatment.

Vegetable soups—pea, asparagus, celery, potato, bean, tomato, are nutritive and appetizing.

When all active rheumatic manifestations have been dispelled, animal broths *on cereals* are adjuncts by stimulating appetite. They are not given for any food value, but as appetizers.

Having secured a clean tongue, all phases of rheumatism vanish with milk as the only food for a proper period; then in due succession, strained cereals, *vegetable* soups, cereal as a vegetable with butter and salt, baked potato, bread, green vegetables, fruit.

Failure in dietetic management in the past, is attributable to excessive use of broths and other animal food; sugar and sweet desserts; the use of alcohol; withdrawal of fruits and cereals.

25 West Thirty-seventh Street.

REMARKS ON THE MANAGEMENT OF FRACTURES INVOLVING THE JOINTS.*

By VIRGIL P. GIBNEY, M.D.,
NEW YORK.

Fractures in and about joints are of perennial interest, hence the title of the paper of the evening calls for no apology. Some there be who may question the propriety of an orthopedic surgeon presenting a paper on a topic of general surgical interest. When one recalls, however, the boldness with which surgeons of all grades of experience invade the domains of orthopedic literature, the speaker on the present occasion will, I am sure, be pardoned for introducing a topic in the discussion of which every member of the Practitioners' Society may easily participate.

The opportunity afforded one having much to do with the problem of giving protection to joints from bones diseased leads him oftentimes to seek protection to joints from bones injured, and the results are, as a rule, so much more satisfactory in the latter class of cases. It has long been evident that the surgical teachings of the day on the management of fractures involving joints are those of yesterday, and that methods dating from a period when perfect restoration of function was not expected, still find a creditable majority who retain a profound deference for tradition. (Take as illustration the use the extension apparatus reinforced by heavily padded side splints.) Many patients with vicious union of the femur appear at the Hospital for Ruptured and Crippled for correction of deformity in the course of the year, and in nearly every instance the history obtained gives this treatment as the one employed. After correction by a linear osteotomy or an open incision with solution of the vicious continuity and suturing of the bones placed end to end, plaster-of-Paris, in the form of circular bandages, is applied with perfect result.

*Read before the Practitioners' Society, November 6, 1903.

We wonder why the prejudice against plaster-of-Paris exists, and the only explanation given is the lack of skill in the use of this valuable agent. Then when we find, after hundreds of subcutaneous osteotomies for hips and knees deformed as a result of tuberculous disease, fixation by a close-fitting plaster-of-Paris bandage all sufficient in maintaining the position desired, we feel that our favorite orthopedic adjuvant is worthy of more consideration at the hands of the general surgeon.

A few years ago a distinguished orthopedic surgeon [Dr. Shaffer] reported a case of fracture of the neck of the femur in an elderly gentleman cured by the use of a traction hip splint, and many of these cases long after the occurrence of the fracture and still disabled have been restored to good use of the limb by the long Taylor hip splint. The late Hugh Owen Thomas, an English orthopedic surgeon of international reputation, claimed good results in fractures of the neck of the femur with a splint known to all as the Thomas splint. Many excellent results by this appliance are already on record. Recently another member of the specialty I represent, and an esteemed colleague, has published a paper in the *Annals of Surgery* outlining a course of treatment of recent fractures of the neck of the femur that promises excellent results.

In his studies of coxa vara, my friend, Dr. Whitman, has found these fractures, complete or incomplete, amenable to the same mode of treatment that yields such brilliant results in bending of the femoral neck. I refer to complete and extreme abduction of the limb which depresses the neck of the femur and forces the trochanter major against the acetabular rim as a firm base of support. This being accomplished, a long plaster-of-Paris spica bandage, applied secundum artium, maintains perfect fixation until union is assured. Then as the limb comes down into normal position parallel with its fellow, the angle of the neck with the shaft is restored and the cure is complete.

Surgeons object to plaster-of-Paris in elderly people, and even in adults who are not elderly, because of the supposed discomfort. In correcting hip deformities in adults by osteotomy, I invariably employ a plaster-of-Paris spica bandage, and after a few days the patients are infinitely more comfortable than they would be in splints assisted by weight and pulley. A stockinette can be applied next to the skin, under this a "scratcher" or two, and over this cotton wool, especially about the bony points, secured by a flannel bandage. Then plaster-of-Paris enough to secure an immobile dressing is applied. One must cut it away where the toilet may be easily managed.

In fractures involving the elbow-joint, the points for consideration are the muscular attachment and the planes of the joint. It must be apparent to everyone that the epicondyle and condyle when separated, while easy to replace, are hard to maintain in this position, and a knowledge of the muscles attached is important when a fixed dressing is applied. Contusions of the soft parts of course interfere with a surgical dressing, but if the dressing be smoothly applied and sufficiently firm to hold the fragments in place, certain chances can be taken in the swelling which must follow. Those who rely on the circular plaster bandage have learned to make provision for this by cutting through the entire length of the plaster bandage and making of it a splint. It is maintained by good surgeons that a position in full extension makes of the olecranon a splint for the condyles, and prevents callous or other deposits in the olecranon fossa, thus minimizing the danger of full

extension as an end result. It is well known, too, that the normal tendency of all joints damaged by trauma or disease is toward flexion deformity.

Hence the importance of recognizing this factor.

An orthopedic surgeon, Dr. Arthur Gillette of St. Paul, Minn., has published, in conjunction with a colleague, a valuable paper on fractures and injuries of the elbow-joint in the *St. Paul Medical Journal* for August, 1902, and in this paper I find the views above expressed.

From personal observation and from a study of statistics I am convinced that full extension is harder to secure later in the management of the case than is flexion. After the union is sufficiently firm, say from ten days to two weeks, the extension position can be changed to that of flexion. This is true in fractures involving the elbow-joint as well as those involving the hip. Where the epiphyses are diseased and the inflammatory process invades by continuity the joint, adhesions are formed before one is prepared, and restoration of function is much more difficult than when the joint is the subject of a simple trauma. An inflammatory reaction of this kind is easily controlled by absolute rest, and the capsular ligament is not so apt to be involved in the short time that rest is necessary.

There are very few joints whose function is not sufficiently understood by medical men, and a little review of one's anatomical knowledge will help out wonderfully in making a diagnosis. This, after all, in the writer's experience, is one of the most important steps to be taken. In looking up hospital and out-patient records, it is astonishing how infrequent are clean-cut diagnoses. The terms, "hip fracture," "shoulder fracture," "elbow fracture," are very common, and I infer that this is the rule in other hospitals. In the hip, for instance, we find bending of the neck of the femur just often enough to make a differential diagnosis far from easy. But the *x*-ray of both hips ought to be conclusive, coupled with a satisfactory history. Within the last few months, three or four cases in adolescents have come under my observation, and the *x*-ray has enabled me to make a diagnosis beyond question. It is only within the last decade that fractures of the femoral neck in children have received sufficient attention to make this lesion an important factor in the differential diagnosis of hip disease. And, fortunately, the methods employed for fixing the joints have been remarkably successful in restoring not only good length but good function.

In fracture above the elbow or knee one naturally expects joint effusion, but it is not at all necessary to look upon this as a contraindication to prompt coaptation. The handling of a joint containing fluid with or without an anæsthetic does not render this condition more rebellious of treatment. If one is afraid of too much distention the sterilized needle of an aspirator ought to enable one to give prompt relief. After this the relative position of the joint surfaces, their evenness or unevenness, can be regulated to a nicety, and one can get a better idea of the exact location of the fragments. If the fragments have disturbed the normal planes of the joints or have produced mechanical obstruction to restoration of function, it is not a dangerous procedure to open the joint and restore the normal relationship of the surfaces, one to the other. The fear of invading a joint by a knife is still prevalent among the best of surgeons. And while it is well to respect this fear, it is a question sometimes whether chances might not be taken.

In fractures involving the ankle-joint, notably Pott's fracture, my attention is called often to an unsatisfactory result long after repair. Many surgeons fail to get a sufficiently long tendo Achillis when the dressing is applied. The foot, in a great many instances, is put up in moderate extension and the tendo Achillis naturally shortens.

As subsequent dressings are employed this defect may be recognized, but the difficulty, if uncorrected, is so apparent that the final correction is left to the masseur. Weak foot and later flat foot result very often, and massage fails to get the tendon long enough. These suggestions may serve to call attention to certain defects in the primary treatment.

The time devoted to bacteriology in medical schools and the surgical technique which is insisted upon ought to ensure safety in the hands of men who are not fortunate enough to get a thorough hospital training to round out their surgical learning. If the coaptation is perfect, then it becomes imperative to maintain the position by whatever means one is most familiar with, but, roughly speaking, there is, in the opinion of the writer, nothing better than the immobilization which a properly fitting plaster-of-Paris bandage affords. The student really gets very little opportunity for plaster-of-Paris work in the medical schools. He sees it applied in the clinics in a manner that does not inspire confidence when he undertakes to apply it himself. The padding is seldom put on smoothly, too much allowance is made for shrinkage, and the plaster bandages are rolled around without much attempt at uniformity. Hence the overriding of fragments even in the shaft of the bone and the condemnation of plaster-of-Paris as a dressing.

Many years ago we had discussions by the late Dr. Sayre and Dr. Frank Hamilton on this very subject—the one enamored of plaster-of-Paris, the other condemning it in season and out of season. Bad results were exhibited on one side, good ones on the other, and *vice versa;* but plaster-of-Paris has survived, and the orthopedic practitioner finds it an admirable supplement to steel braces and splints of all kinds. In our work at the Hospital for Ruptured and Crippled we have found it necessary to employ trained assistants in plaster work, because the workshop cannot begin to turn out with sufficient promptness the splints that are needed. The members of the staff, therefore, grow quite proficient in the use of this agent, and finding it so efficient in the control of spasm about a diseased hip or knee or ankle, they wonder, as does the writer, that the general surgeon does not use it more in his own practice. The surgeons in charge of the hernia department have long since learned to recognize its value over dressings after hernia operations, especially in children, and it is seldom that a patient leaves the operating room without a plaster-of-Paris spica bandage. If the operator, as is the case sometimes, objects and declares plaster unnecessary, the staff and nurses find it very difficult to care for the child so as to avoid infection.

Reasoning therefore from its value in joint disease and in the maintenance of good results after osteotomies, we claim that recent fracture could just as well be managed, with, of course, a little more care after its application.

It is hardly necessary at this time to occupy your time with a protest against passive motion after fracture. My impression is that it is the consensus of surgical opinion that passive motion is no longer tolerated. If, after a reasonable period of active motion and devices that will encourage active motion, deformity still exists, an anæsthetic would best be employed to overcome such deformity.

My paper, therefore, amounts after all to a further plea for plaster-of-Paris as a dressing for fractures,

a comparison between joint injuries from trauma and those from disease—the harmlessness of one, the ravages of the other.

16 Park Avenue.

THE PRINCIPLES OF DIAGNOSIS OF MEDICAL MALINGERING.*

JOHN PUNTON, M.D.,
KANSAS CITY, MO.
MEMBER AMERICAN NEUROLOGICAL ASSOCIATION, EDITOR INDEX-LANCET, ETC.

The markedly increasing prevalence of medical malingering, as well as the serious difficulties which at times beset its detection, render its study of the highest importance. Indeed at any moment and in any class of medical practice we may be confronted by feigned disease or lesions induced by factitious means, and failure to recognize them may entail most serious consequences not only to our reputation as physicians and surgeons, but also to the individual or corporation who solicits our professional services.

It is, therefore, extremely fitting that we devote sufficient time and labor thoroughly to familiarize ourselves with the cunning methods of medical malingerers, and thus protect and fortify against the chagrin and ridicule that will surely follow our failure to detect their sly tricks.

The marvelous ingenuity displayed at times by these crafty rascals in practising their deceptive art, and the great success which attends their efforts at the present time, should tend to stimulate us to even greater effort and more effective service in this department of medical science. That medical malingering constitutes one of the most formidable evils of the present age is well understood, but its peculiarly increasing successful practice would seem to reflect upon the ability of the medical practitioners to detect its fraudulent character. Moreover, its growing successful practice has proved to be a great temptation for new recruits, hence many accessions are annually added to the ranks of these miserable deceivers, who having carefully planned and studied their methods of fraud as well as invented many ingenious modern novel tricks, and devices designed solely for the purpose of defeating the most thorough and painstaking scientific medical examination, thereby aim to deceive not only the physician but also all those who are brought in contact with their nefarious practice. In view, therefore, of the unlimited field of action which medical malingering enjoys, together with the diversified character of its manifestations, its detection is rendered, even under the most favorable circumstances, exceedingly difficult, and at times well-nigh impossible. Fortunately, however, there are certain general principles which greatly aid us in its diagnosis, and when these are used in conjunction with accurate knowledge concerning the anatomy and physiology of the parts affected, together with the pathology of the diseases incident to these organs, the problem which confronts us is thereby greatly reduced. Upon investigation it has been found that the underlying motive in the large majority of cases of feigned disease can be directly traced to the advantages which accrue to the various kinds of personal gain. This may present itself in the form of conceited notoriety, monetary acquisition, or as shirking responsibility for crime and other misdemeanors which arise as the result of vicious or thoughtless conduct. In order, however, that the principles which govern its diagnosis can be better understood, it is necessary that we reduce all forms of medical malingering to a systematic order of classification, as the same rule does not apply in all cases. By a careful analysis it has been found that the various modes in which feigned disease appears, although exceedingly complex in their clinical manifestation, are capable of being reduced to three classes.

1. The first consists of cases in which the patient under some morbid impulse or fear *involuntarily feigns* disease, as seen in some forms of hysteria or neurasthenia.

2. The second class includes cases of *voluntary exaggeration of real morbid symptoms*, or manifestations superadded to genuine ones, including deficient powers of subjective analysis.

3. The third class embraces cases of deliberate and *distinctly planned deceit of factitious disease*, or purely voluntary morbid creations, thus constituting unadulterated intentional fraud or medical malingering of the worst type. The clinical application of this simple but comprehensive classification will greatly aid us in the diagnosis or detection of all the varied forms of medical malingering by the process of exclusion and elimination.

1. For instance, we have all seen cases in which it seemed impossible to decide (at least at the outset) whether the victim of an accident was a pure malingerer or had become through the fright and shock experienced by some injury or morbid impression a *genuine hysteric or neurasthenic*. Now it cannot be denied that such cases are sometimes the result of an inherent or latent neurotic diathesis, so that what at first appeared to be a pure imposition is upon further critical investigation found to be a genuine psychoneurosis of traumatic or other origin. These conditions are, therefore, feigned not by direct action of the will, but through an inability on the part of the individual to resist the promptings of an unstable and excitable nervous system, such as is commonly associated with hysteria and neurasthenia. Not all forms of feigned disease, therefore, are necessarily fraudulent in character, nor are its victims always responsible for its appearance, hence in the detection of medical malingering it is well to bear in mind that what at first may appear as a genuine case will later prove to be the result of latent hysteria or a purely neuromimetic neurosis.

Such cases, therefore, belong to the first group of our classification, and in their diagnosis we must apply the general principles which obtain in the differentiation of organic from so-called functional disease, by reference to the cause as well as the mutability of the symptoms, in which case grave troubles suddenly disappear and give place to others, such as could not result from the same organic cause.

2. Under the second class of cases we must endeavor to recognize the motives which may exist for a patient whose illness is, or has been, real, to extend or become prolonged beyond the period of his supposed incapacity for work by feigning graver or added symptoms. Thus we find sometimes a patient receiving weekly or monthly benefits during some incapacity following a real injury or illness, and who may, by refusing to duly exercise his recently recovered member, or through some indolence or indifference on his part, purposely neglect to submit himself to the prescribed treatment, and thus, by his insubordination or deception, induce deformities or complications that may not only further his stay in the hospital, but wholly incapacitate him for future usefulness. This is usually done in order to shirk his work or the duties incident to his usual occupation. He is, therefore, lazy, and malingers in order to prolong his idleness. Hence, we find real injuries, such as fractures, are sometimes delayed in their recovery by ill-conditioned men who disturb and even remove the splints. A diabetic patient

*Read at the annual meeting of the Mississippi Valley Medical Association, Memphis, Tenn., October 8, 1903.

has been known to place cane-sugar in his urine in order to prolong his stay in the hospital. Even in my own experience the following conditions have come under observation in the form of malingering for the purpose of shirking responsible duties or for personal gain, but which were fortunately discovered, viz. feigned blindness, deafness, aphasia, paralysis, epilepsy, tremor, ankylosis, hæmatemesis, and insanity. Numerous other instances could be cited as occurring in the practice of other physicians, but we are all familiar with the truth that every form of deception is sometimes resorted to for the purpose of gaining certain pecuniary benefits or the avoidance of certain responsible duties. Indeed, of all the difficult varieties of malingering, those which belong to this second class are by far the more frequent and common, while their manifestation presents the most complex forms of both organic and functional diseases; but it is the latter or functional conditions that is found to be by far the more frequent form in which they appear, while the resulting morbid phenomena are largely of a subjective character.

This, therefore, renders the diagnosis more difficult, but as before remarked, the underlying motive must be carefully studied, and by close attention to the progress of the case, mistakes will often be prevented, more especially when the symptomatology is found not to conform to certain well-defined scientific medical laws.

3. The third class comprises all cases of deliberately planned or premeditated forms of medical malingering. In such cases the simulation is the expression of unmitigated imposture and fraud. It is, therefore, a voluntary morbid creation which occasionally is so well planned and executed that it baffles all efforts put forth to detect its fraudulent character.

Indeed, its conscious purposeful action renders it the most malicious and damnable of all the varied forms of medical malingering, besides proving to be the most difficult of detection. The desperate lengths to which these miserable impostors will go at times in order to deceive not only the layman, but the doctor, can hardly be conceived or believed, while the severe and painful torture which its practice entails does not seem in the least to be a restraining factor, even when the certainty of actual death is known to be the penalty in the event of detection and exposure of their infernal methods. It is to this class of miscreants more especially that I desire to call your attention, as it is my belief that they are greatly on the increase, and while no form or class of business men or corporation are exempt from their fraudulent schemes, yet the railroad companies, perhaps, of all others, are the greatest sufferers from the stealthy impositions of these human pests; it is, therefore, fitting that we as medical representatives not only familiarize ourselves with their slick methods, but also try and devise means and measures by which we can not only detect but expose their sly tricks, and thus better protect the great and varied interests which we, at times, are called upon to minister. In order to show the unique methods by which insurance and railroad companies are swindled by such malingerers, a brief reference to the statements by "Moffett," who is considered one of the stars in this line of fraud, is all that is necessary. He states that he could recall at least seventy schemes that he himself worked successfully. The methods he used varied considerably, but included tight bandaging of normal limbs, and then pounding the same in order for them to swell and appear badly injured. The use of shot on the floor of a street car, and then stepping on same in order to fall and feign serious injuries. The cane, and screw racket, by which he would file the ferrule of his walking stick to represent a screw-driver, then he would loosen the screws that held the iron plate of the outside step of the car, and by stepping on same would fall to the ground, and claim serious damages. These and many other schemes he worked successfully for many years, and claimed that he made it a universal rule to employ the very best doctors, as he found, by experience, that they were the most easily fooled, while the companies he fleeced were better satisfied with their opinions. In this connection he also states that he paid the doctor bills promptly and willingly, even though at times he thought they were exorbitant, but this was done, he said, in order to impress them with the honesty of his actions. (See *Kansas City Medical Index-Lancet*, August, 1903.)

With a desire to place this subject before you in as practical a manner as possible, you will pardon me if I take occasion at this juncture to recite briefly a case that has recently come under my observation, and one which beautifully illlustrates many of the points referred to, besides offering a favorable opportunity to emphasize the more important principles which governed the diagnosis of this most difficult form of intentional medical malingering.

On the 28th day of August, 1902, Oran Hoskins, aged twenty-two, while leaning in the car door at Fort Worth, Tex., claimed to have been struck in the back of the head and knocked senseless to the ground by the car door, which was supposed to have been fastened to the ceiling with an iron hook, and jarred loose by switching. Two witnesses testified having seen Hoskins injured, and they at once went to his aid and claimed they found him unconscious and in convulsions. Later physicians appeared on the scene who ordered him taken to a sanatorium, where he remained three weeks, during which time he became violent and had to be restrained to his bed by straps. At the end of the three weeks his mother took him home, and what took place there for the next three months is not known to the world. Suit, however, was soon filed against the railroad company for the large sum of $75,000. In December, which was four months after the alleged accident, the first trial took place. The lawyers for the plaintiff claimed that Hoskins's injuries were of a serious and fatal nature, that his death was expected at any time, and with this view the attending physicians concurred. Their diagnosis at this time was that he had received a serious cerebral concussion, complicated with hemorrhage and extensive laceration of the brain tissue, which rendered him not only insane, but beyond hope of recovery, and his death might be looked for at any moment. A doubt arising in the minds of the jury as to the amount of damages such a person should receive resulted in a hung jury.

On February 26, 1903, or six months after the alleged accident, Dr. Cale, the chief surgeon, and myself were called to Fort Worth, Tex., to examine the patient.

Upon entering the room we found him lying in bed, and I ventured to ask him his name, when his mother informed me that he was unable to speak or understand anything that was said to him, and this had been the case, she said, ever since the injury. I asked him to sit up in bed, but he refused to do this, his mother stating that she always helped him to do this. She then did so and he sat up. He began at once to move his head in all directions, at the same time made grotesque movements with his hands and arms, which was also attended with a wild, vacant stare. I again began to question him, but he refused to answer me, his mother, however, remarking that he could not hear very well, and she doubted if he

could see well at all times. His constant movement of all four extremities led us to conclude, however, that there were no motor paralysis, nor could we detect any cranial or other palsies. With the aid of his mother we got him out of bed, and he was able to stand alone and he walked with slight assistance. Upon stripping him we could discover no marks or scars, and there was no external evidence of there having been any injury to his head. The muscular system showed no signs of genuine atrophy, and the muscular tonicity was good. As we were unable to receive any assistance from the patient himself, our examination, scientifically speaking, was necessarily incomplete. Hence, we were unable to test the sensory functions, but we learned from the mother that he did not complain or seem to suffer; that his bladder and rectal functions were not seriously impaired, although he was somewhat constipated. There were no bed sores, or other evidence of vasomotor disturbance. The superficial and deep reflexes were slightly exaggerated, but there was no ankle clonus or babinski reflex present.

We were unable to test the stereognostic sense. In regard to the special senses, there were no ocular palsies that we could detect. The pupils were enlarged, however, and glaring, but responded to light. The hearing was said by the mother to be impaired, but from our observation of the patient we had already formed an opinion that he could not only see and hear what we said, but also understand all that was done concerning him. This, however, was contrary to the general belief and opinion of all who had so far seen or examined him. Examination of the heart, lungs, and other visceral organs revealed no organic disease, although the heart action, as well as the respiration, were both accelerated. The pulse was 100, but the temperature was normal. We learned from the mother that while the patient had to be fed like a child, he enjoyed a good appetite, could lick his lips with his tongue, and slept without medicine. Mentally, the patient had an apparently dull, apathetic, stupid, vacant, demented stare, but after spending about one hour in our examination, Dr. Cale and myself both came to the conclusion that the patient was *malingering*. I was then requested to send the result of our examination in the form of a written report to the chief surgeon, and through him to the legal department, which I did. In this I embodied the special features of our examination, besides giving reasons for our diagnosis and which will be referred to later. On March 2 I received a telegram calling me to Fort Worth to appear as a witness in the trial of the case. After the usual preliminaries, the medical witnesses for the plaintiff were called to the stand. Their testimony went to show that Hoskins was seriously and permanently injured, and that he was considered by them as being idiotic, demented, and insane.

That at the beginning he had received a blow at the back of his head which produced cerebral concussion, with consequent loss of consciousness, later attended with convulsions, and then he rapidly lost the use of all of his mental faculties, including speech, which indicated to them that he also suffered cerebral hemorrhage, and laceration of the brain tissue which was sufficient to deprive him for all time of the use of his mental faculties; that he was compelled to be nursed and treated as a baby the rest of his life; that he was wholly oblivious of his surroundings; that he had been deprived of all mental life and he was now living a vegetative life: for all of which they claimed he was entitled to serious damages.

During the testimony of Dr. ——— the patient was wheeled into court and presented to the jury. His apparently pitiable condition made a profound impression upon them, especially as he made the same grotesque movements with his head, arms, and body and had the same vacant, glaring stare in his eyes as when we examined him. The effect on the jury was plainly visible, more especially when the lawyer asked the doctor the following questions:

Now, doctor, is this the young man you have been testifying about?

A. Yes, sir.

Q. What is his mental condition now?

A. I consider him in a state about like a child that has never been taught or learned anything. It is almost—well, it is idiotic: it is perhaps worse than idiotic, he has practically no mind, that is the size of it.

When this answer was given I saw two jurors break down and cry and I nudged Dr. Cale and said to him, "Doctor, we have lost this case already before we testify." It is needless to add that when I was called to the stand I took exactly the opposite view of Hoskins's case to that of the other physicians. In my testimony I claimed that Hoskins was a malingerer; that he was not as badly hurt as he wanted people to believe; that he was fooling not only the lawyers and doctors, but also the court and jury, as well as the citizens, and that my judgment prompted me to believe that he would rapidly recover: all of which subsequently proved to be true. In spite, however, of my best efforts to convince the jury that he was a malingerer, they awarded Hoskins a verdict for $35,000, the largest ever given in the State of Texas. Two weeks later the railroad company asked for a new trial, which was refused. Then followed the most sensational features connected with the case. No sooner had the motion for a new trial been overruled than Col. R. M. Wynne, one of the most prominent lawyers at Fort Worth, Tex., went before the court and made the following statement, viz.: "That Mrs. Hoskins had visited him at his office some days before the accident happened, and had asked him what damages could be recovered from a railroad company in case an accident happened to a young man by which he should be rendered unconscious and become like an idiot, or lose entire control of his mind. Supposing that she was stating a hypothetical case, Colonel Wynne said he talked with her about it, and subsequently she asked him to visit her at her home, which he did, and there met the son, Oran, who talked with him about such an accident and indicated that such was to be carried out. Subsequently Mrs. Hoskins called again at his office, and when the door was closed told him she had made up her mind to go through with such an accident to her son, and wanted him to agree to take the case; that he remonstrated with her then and there, and told her that he would not take such a case for all the gold that could be dug out of the ground, and he warned her not to undertake it. That she left saying that her mind was fully made up to try it, and that she would consult some other lawyer. She departed, and he at once told his law partner, Mr. C. R. Bowlin, of the interview, and they agreed to say nothing about it, hardly supposing that it would amount to anything. That a few days later he was surprised to read in the newspaper of just such an accident as had been outlined to him, and that he was again spoken to by Mrs. Hoskins about it. That he held his peace; that he did not tell Carlock and Gillespie about the interview Mrs. Hoskins had had with him, after he knew they had the case, because, as she had asked him where to find Mr. Carlock when she left his office on the occasion of her last interview with him before the accident, he supposed she went right to him and

consulted him about it. When the trials came on he said nothing, and when at last he saw that the case had been won in the court here and would go up to the higher court, he decided it was time for him to speak, and so he told his secret, and absolved his friends from obligation to keep it further."

When this statement had been made to the court, Messrs. Carlock and Gillespie, attorneys for the plaintiff, at once denied in open court all knowledge whatever of the woman and her fraudulent schemes, and later, when they became fully persuaded that the case was not what they thought it was when they undertook it, they gave it up entirely, and at this writing they have no connection with the case whatever, they having withdrawn in favor of other lawyers.

Mrs. Hoskins also denied emphatically all that Col. Wynne had stated about her consultation with him previous to the alleged accident. Judge Dunklin, however, set aside the verdict at once and ordered a new trial, at the same time turned the patient over to the physicians for further investigation, and they removed him to the sanatorium. No sooner had Hoskins reached the sanatorium than the same physicians who testified in his behalf in court began to subject him to certain tests (which have already been published in the *Kansas City Medical Index-Lancet*), and which consisted in brief of first impressing the patient with the seriousness of his condition and telling him that nothing short of a severe and radical operation to his brain would do him any good and even this would likely prove fatal. In the meantime, every preparation was made for the operation by the other physicians in the presence of Hoskins, by the display of instruments, etc., all of which was intended to impress upon Hoskins the seriousness of the undertaking; finally he was placed upon the operating table, when a bogus anæsthetic was first administered but substituted later by genuine ether, and which soon resulted in Hoskins confessing his fraud by admitting that he had been shamming insanity for over nine months. When the results of this startling investigation reached the ears of the legal officials of the railroad company they sent me the following telegram: "Dr. John Punton, Kansas City, Mo. Oran Hoskins under test by Dr. Walker confessed his fraud last night. You are vindicated." (Signed) West, Chapman & West, Attorneys.

Simultaneously with these events Oran Hoskins and his mother were indicted by the grand jury for conspiring to swindle the railroad company, and as soon as the results at the sanatorium were received they were placed under arrest and are now under heavy bonds to appear to answer the charge. As it now stands, a new trial has been granted the company, and the plaintiff and his mother are under bonds, waiting for the time to arrive set for their hearing. What will be the final outcome of this greatest of medical frauds remains to be seen, but it is to be hoped justice will finally prevail.

It may now be pertinent for us to inquire what methods or principles were applied in the detection or diagnosis of this most difficult and important case.

In the absence of any known specific tests all authorities agree that the leading principle in the diagnosis of fraudulent or simulated insanity is the usual presence of *marked inconsistencies* in their conduct or behavior, hence the malingerer will unwittingly expose himself in some exaggerated manner. Without any desire to exalt or underrate unduly the value of this great practical principle, I am convinced that there is an intuitive knowledge born of large clinical practical experience and training with the insane which enables the possessor to recognize as well as interpret the true significance of such inconsistent overaction or simulation when brought in contact with it, and which cannot be acquired solely from textbook knowledge. Indeed, it was the application of this principle that led us to discover the fraud, for when I saw and studied the grotesque and exaggerated movements, I was convinced that they were consciously assumed or simulated, and therefore under control of the will. The patient was, therefore, "overplaying his part" as an insane man. Moreover, it is now a well-established principle that simulation or malingering often presents clinical pictures which in themselves are medical contradictions. Hence, they do not conform to known physiologic, pathologic, chemic, symptomologic, or other medical laws, consequently their fraudulent character is usually capable of demonstration when subject to the various tests belonging to the more approved and perfected methods of modern medical science. For instance, feigned blindness can hardly resist the test of the ophthalmoscope when directed by a master of ophthalmology. The stethoscope, endoscope, and sphygmograph will reveal the true condition of the heart and lungs. The various microscopical and chemical tests will clear up a doubtful diagnosis of kidney and other lesions. Electricity will aid the diagnosis of feigned paralysis and other anomalous nervous symptoms. The use of chloroform, ether or other anæsthetic will, when judiciously applied, often prove a valuable aid in the diagnosis of doubtful morbid phenomena. Rigid isolated medical surveillance will often reveal deceptive methods. When these and other recognized agents are judiciously and skilfully employed and associated with a thorough knowledge of the motor, sensory, reflex, trophic secretory, visceral and psychical or mental mechanisms of the nervous system, the demonstration of actual pathological lesions is greatly aided, while the differentiation of the false from the true, the genuine from the counterfeit, becomes largely a question of logical deduction. In the diagnosis or detection of simulation, therefore, the physician and surgeon is called upon to show how far the clinical picture conforms to known medical law and practice by the application of all the various factors to which allusion has been made.

When the case before us was subject to the scrutiny of this great practical principle it was found to be in itself a medical contradiction. For instance, here was a man that, according to medical opinion, had received a severe blow at the base of the brain, with consequent loss of consciousness and attended with convulsions, which later culminated in mania, and subsequently presented a complete loss of his mental faculties, including speech, for a period of at least six months at the time of our examination.

The pathological condition, according to the testimony of these physicians at the first trial, agreed that there was cerebral concussion and hemorrhage combined, with serious and extensive laceration of brain tissue. The lesion, however, was located by Dr. —— in the second and third convolutions of the left side. which corresponds to Broca's speech center. Reference, however, to the symptomatology is all that is needed to show this to be a mistake, for if the supposed lesion was confined to this region, motor aphasia would be the inevitable result. But the feigned symptomatology was designed to show the presence of not only an inability to pronounce words, but also a complete absence of their memory. Hence the clinical picture was intended to affirm the presence of word deafness, word blindness, alexia, agraphia, and indeed all forms of both sensory or amnesic and motor or ataxic aphasia, including psychical blindness and deafness, as well as that form of insanity known as dementia. Hemorrhage, there-

fore, was the most plausible theoretical pathological diagnosis. By analyzing the symptomatology, however, the hemorrhagic lesion, if present, could not possibly be solely confined to Broca's speech center, but should involve other parts of the brain, notably the first and second temporal, lesions of which give rise to word deafness and occipital lobe injury or which may produce word blindness. Furthermore, if the lesion was confined to the left speech center, then the emotional involuntary or automatic centers would not be wholly destroyed, as these are largely represented and subserved by opposite hemispheres. For instance, in case of serious injury to the left speech center, even when there is total loss of voluntary speech, the corresponding center on the right side not only may continue to exercise its emotional and automatic functions and allow the patient to express himself in the form of gesture or other pantomimic kinds of language, but also is capable of being educated to supplement the action of the injured opposite side, and thus, by a process of compensation, in due course of time will restore the ability to give expression to not only pantomimic but other forms of language. The extent to which this supplemental or compensatory action of the undamaged speech area is possible varies greatly, but, according to "Herter," is sometimes very astonishing. It was, therefore, only reasonable on our part to look for some improvement in this direction at the end of six months, as all authorities claim such to be the rule, but the case in question presented no apparent improvement; its absence, therefore, would seem to favor the view of simulation. Moreover, according to "Ranney," in order to pronounce any word it is essential that both the cortical center of speech and also the nuclei of origin of the facial, glossopharyngeal, pneumogastric, and hypoglossal nerves which are associated with it must be called into action. Inasmuch as the patient appeared unable to speak or use any form of language, it was only reasonable for us to look for some such cranial nerve involvement due to pressure; but these were entirely absent, unless it could be claimed that the auditory and optic nerves were injured and thus accounted for the alleged statement of the mother that her son was somewhat deaf and blind. But Dr. Cale and myself were well satisfied that the patient could not only see and hear but understand all that was said and done in our examination, hence word deafness, word blindness, alexia, and agraphia were excluded, besides other symptoms of aphasia, as well as dementia. Further analysis of the case also revealed the fact that there were no involvement of the bladder and rectal functions, and no true atrophy of the muscles, while the reflexes indicated only a slight functional disturbance. Examination of the heart and lungs found them to be in a good condition, as well as the rest of the viscera; indeed, all organic diseases were excluded. In addition, there were no external marks or scars of any injury or fracture having been received to the head or skull, which also confirms the suspicion given expression to by the railroad officials at the outset, viz., that they doubted whether Hoskins received the injury he claimed, and certainly in the light of recent developments it would seem he did not receive any such injury. When these facts are taken in connection with the close watch instituted by Hoskins's friends to prevent any railroad medical representative to see or examine him for so many months, besides the absence of any rigid medical isolated surveillance having been enforced, together with the suspicious character of his home environments, and crafty attitude of the mother, all tended to not only favor our view of the fraudulent character of the symptoms, but also favored the correctness of our diagnosis of medical malingering. Moreover, these facts can now be supplemented with others brought out at the trial as well as the later disclosures, not forgetting the amusing incident testified to by one of the doctors and illustrated by him upon the patient to the jury while in the courtroom, viz., that Hoskins's conditions could readily be made worse and his symptoms greatly exaggerated by shaking a red piece of cloth or handkerchief in his face, which, when done, had the same effect upon Hoskins as it does upon a bull, whereby the animal becomes greatly excited and enraged, thus proving to our mind at least the conscious simulation of the symptoms by Hoskins. In the light of all this evidence, as well as the fact of his sudden or instantaneous recovery, I think you will agree that the diagnosis of medical malingering was not only justifiable but clearly confirmed. In conclusion, it is interesting to note that the principles upon which it was based, although few in number, are subject to indefinite expansion and variation, according to the demands of each case.

In their recapitulation we find that they consist in the application of the following rules:

1. The recognition and correct interpretation of inconsistent morbid physical and mental phenomena.

2. By the exclusion and elimination of disorders with which the symptomatology does not agree.

3. Their disassociation with known lesions of all kinds. These, then, constitute the chief elements which form the principles that govern the diagnosis of medical malingering. In their practical application, however, they at times embody the use of all the various methods known to medical science, while their successful utilization constitutes not only the chief function but also the highest art of the clinical diagnostician, when brought in contact with abnormal conditions said to be due to traumatic influences.

When these m re perfect methods and principles, based as they are upon a more rational knowledge of the cerebrospinal architecture and other organs of the body, are duly compared with our former more faulty ones, based as they were upon incorrect knowledge, and erroneous inference, the practical benefits which accrue to the more modern medical knowledge and technique can be readily understood, while their universal application to the study of trauma and its evil effects upon the animal economy will not only revolutionize our skill and power in the detection and exposure of all the varied forms of medical fraud and malingering, but tend to raise the standard of medicine to the lofty eminence and dignity of an exact science.

High Frequency Electric Currents in Therapeutics.—J. Hall-Edwards states that there is hardly a disease extant in which high-frequency currents have not been applied, and from the glowing reports circulated one would imagine it to be a panacea for all diseases (except housemaid's knee). Experience has taught him that its virtues have been vastly overrated, and that, although it has its uses, they are certainly limited. In his hands the best results have been obtained in obstinate neuralgia, dilatation of the stomach, hemorrhoids, gonorrhœa, gleet, leucorrhœa, and in the relief of pain in cancer. He has used it with some success in the treatment of various skin affections, and in chronic prostatitis. Of its effects in phthisis he has had little personal experience, but as many well-known continental workers have reported favorably upon it, one must credit their assertions.—*Treatment*.

CONGENITAL ORBITAL SARCOMA OF ENDOTHELIAL ORIGIN IN AN INFANT. OPERATION AND PRESERVATION OF GLOBE.*

By MORTIMER FRANK, B.Sc. (Mass. Inst. Tech.), M.D.,
CHICAGO, ILL.

The literature of orbital sarcoma, especially in young subjects, is extensive, but congenital orbital sarcoma of endothelial origin is certainly not common. In a careful study of the literature on the subject I have not found a case, hence I report this one in the belief that it is unique. A great diversity of opinion exists on the subject of endothelioma, as regards not only its exact place in the oncologic system, but also its clinical and anatomical significance, leaving many important and numerous questions still unsettled. In many instances it is difficult to decide, from the structure of the tumor alone, whether it is an endothelioma, sarcoma, or adenoma. Some prefer to class them as sarcomata, while others describe them as embryonal adenosarcomata. The most striking feature common to this class of neoplasms is the combination of cellular and connective tissue elements, sometimes one predominating and again the other.

Of the clinical history of this case, all that is essential may be summarized as follows:

Examination: The patient, a male infant, was eight weeks old when first seen on September 12, 1902. The parents were healthy, and the mother, a primipara, said gestation and labor had been normal. At birth a swelling at the inner part of the left upper lid, producing a slight protrusion of the left eye, was noticed, and had about the same appearance then as it had when brought in for examination. The infant was well nourished, and physical examination showed no disease of the other organs. On examination, there was found beneath the upper lid of the left eye, between the internal angular process and the supraorbital notch of the frontal bone, occupying the inner wall of the orbit, a growth, the subconjunctival surface of which was about the size and shape of the end of a large peanut. The tumor was smooth, tense, not nodulated, and when steady pressure was made upon it no pulsation nor recession was felt. The integument of the upper lid was of natural color and unattached, but, owing to the presence of the neoplasm, the lids were not tightly approximated when closed. The left eyeball slightly protruded, and was displaced downward and outward. Globe movements were limited. There was no œdema of the lids and no injection of the ocular conjunctiva. The pupil was dilated and the iris reacted slowly to light. Ophthalmoscopic examination was negative.

Operation: Under chloroform anæsthesia, the bulbar conjunctiva was opened directly over the external surface of the tumor, the eyeball itself being left *in situ*, and carefully freed from its attachments for some distance. The growth was found to be firmly adherent to the sclera, and was separated by gentle dissection. The neoplasm was found to be encapsulated and a needle was introduced into the sac, but nothing could be withdrawn. This precaution was taken, with the idea that the mass might prove to be an encephalocele. In order to facilitate its removal, the internal rectus and superior oblique muscles were severed. The sac was then opened, and the contents, which resembled brain tissue, both in color and consistency, removed with a small, dull curette. After the sac had been emptied, the portion adhering to the inner wall of the orbit was explored for a possible opening into the cranial vault, but none could be found. A ligature was tied around the proximal or attached end and the sac cut away beyond it. The severed muscles were approximated and sutured, and the opening in the bulbar conjunctiva closed. Two weeks after the operation, the little patient was taken to his home, in Wisconsin, with the eye slightly converged, but otherwise normal. I am informed that the child is healthy, and that the only evidence of an operation having been performed is the slight convergence which still persists. (September 15, 1903.)

Macroscopical Examination: The tumor was enclosed in a fibrous capsule, and measured approximately 10mm. in thickness, and about 2 cm. in length. It was grayish-red in color, friable in consistency, resembling normal brain tissue, and similar in shape to a sausage. It had no pedicle, but was attached at its proximal end by numerous bands directly to the periosteum of the inner wall of the orbit.

Histological Examination: The tumor was preserved in alcohol and imbedded in celloidin and paraffin. Sections were stained in hematoxylin and eosin, safranin, Van Gieson's stain, thionin, and Unna's polychrome methyl blue.

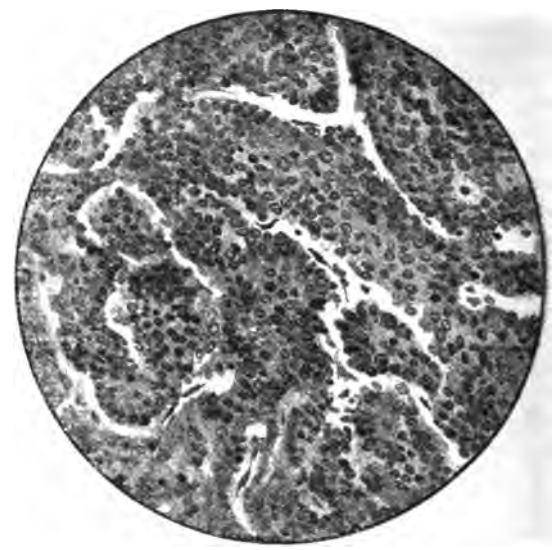

Fig. 1. Shows the alveolar arrangement and the large number of cell masses bounded by anastomosing fibrous tissue.

Viewed as a whole, with a low power (Fig. 1), the tumor is composed of a large number of cell masses, bounded by more or less complete anastomosing bands of fibrous tissue, so that an alveolar arrangement is produced. The alveoli, however, differ widely in size and in proximity to each other, and are not perfectly solid. On more careful examination it is clearly seen that the alveolar masses are formed by a somewhat complete double row of cells (Fig. 2), the long axes of which lie in line with the radii of the alveoli. The center of the alveolus within this stockade of border or covering cells is occupied by similar cells, which are not regularly arranged nor so closely packed together. These cells, as a rule, are not firmly connected with the lining ones, but lie free in the open spaces. More commonly, however, the alveolar structure is not so manifest, for there are large areas in which the proliferating cells are so closely packed together that the alveolar arrangement is lost and only a narrow streak of stroma is seen to traverse its center. This probably does not indicate a marked deviation from an alveolar structure, which the tumor certainly possesses, but rather a packing together or a coalescence of smaller alveoli, which has occurred in the course of its growth. Coming to the cells proper of the tumor, one observes a striking monotony of appearance. The cells in general are cuboidal, but when they are not closely packed together are decidedly

*Read before the Chicago Ophthalmological and Otological Society, October 13, 1903.

cylindrical. The nucleus of the former is round, while that of the latter is oval and often elongated. All of the nuclei are vesicular, and possess a considerable amount of granular chromatin scattered in small masses evenly within them. One or more deeply-stained nuclei can usually be demonstrated. The cells possess, in general, a comparatively small granular body of protoplasm, except the cylindrical cells, which have a more extensive cytoplasm. Here and there a cell will take a heavy stain, the nucleus

Fig. 2. An alveolus under high power, showing its formation of a double row of cells.

being large, and presenting every appearance of being in a state of mitotic division. An attempt at bringing out karyokinetic figures proved unsuccessful. This was probably due to the alcoholic fixation or to the slow growth of the tumor, as shown by the clinical course. In some of the alveolar spaces the cells have undergone degeneration. The cellular territories just described are bounded by tracts of connective tissue which, although not abundant, really form the structural framework of the tumor. This basement membrane, varying in thickness, forms a network with wide and irregular meshes in which the cellular elements lie. With Unna's polychrome methyl blue the connective tissue element stands out conspicuously, and while the cells within the alveolar spaces have but few fibers between them, it can readily be seen that at the circumference the covering cells are supported by bands of interstitial tissue carrying numerous blood-vessels. The stroma consists of loosely arranged fibers, with long, spindle-shaped or oval nuclei. Between these fibers are gaps and spaces which are occupied by red blood cells and occasionally by a few of the tumor cells. Within the stroma are seen vessels lined by a single layer of cells, identical with the tumor cells of the alveoli, representing a process of lymphangiectasis in which, as yet, no cell proliferation has occurred. Whether these be blood or lymph vessels, they seem to be conclusive proof that the growth is of mesodermic origin. The alveolar masses described above represent a proliferation of either blood or lymph vessel endothelium, and where they have coalesced, this proliferation has broken through its normal boundaries, in consequence of which a general invasion of the cells has occurred.

Those portions of the neoplasm that contain the typical and well-marked alveolar structure lined with the double row of cells, which are probably dilated lymph vessels (lymphactasia), might suggest adenoma were it not that the development of these tubular structures forms an almost complete and uninterrupted picture from the beginning of proliferation in the small gaps or lymph channels up to the apparently atypic and irregular masses of cell material. From the foregoing, it seems probable that the tumor is a congenital alveolar sarcoma of endothelial origin.

Histogenesis: The probable histogenesis of the growth is as follows: Early during the invagination of the mesodermic portion of the primary optic vesicle in the formation of the primary optic cup, a diverticulum grew forward from it, and later on became cut off from the parent structure. The imprisoned mesodermic tissue surrounded by mesenchyma began to proliferate, leading to the structure which the neoplasm shows.

Remarks: In the classification of these tumors, although their exact place is still *sub judice*, their embryonic origin is a fundamental consideration. In the simplest embryonic form of cell growth, all cells are alike, and, according to Thiersch and Waldeyer, if endothelium is of mesodermic origin and as such belongs to the connective tissue group, then endothelioma must belong to the class of sarcomatous tumors. A fuller discussion of this question does not come within the scope of this paper.

In a tumor which is encapsulated and slow-growing, there is always some question as to malignancy. The accepted criterion of such tendency, namely, unbridled growth of embryonal cells and their recurrence after removal and tendency to form metastases, is sometimes at fault as to each and every detail. Embryonal-celled tumors are sometimes not malignant, as, witness teratomata, while, on the other hand, mature-cell tumors are sometimes malignant, as witness fibroids. In time, back of this criterion, which is really not cause but effect, will some time be found an etiological factor that will become the test of malignancy. Nevertheless, at the present time any tumor composed of embryonal connective tissue cells and not inflammatory in origin must be called a sarcoma, whether encapsulated and slow-growing or the reverse.

My acknowledgements are due to Dr. A. J. Behrendt for referring the case to me, and Dr. W. A. Evans for many valuable suggestions.

Multiple Angiomata of the Spleen.—Dr. Wm. C. Pumpelly, pathologist to the Georgia State Sanitarium, Milledgeville, Ga., reports a curious post-mortem finding in the case of a negro woman who died of pulmonary tuberculosis. The spleen was considerably swollen and on section presented a number of vascular areas, about 3 cm. in diameter, which were found to be composed of blood-vessels, supported by a delicate connective-tissue framework; they were distinctly circumscribed and separate from the spleen tissue. There were possibly twenty in all.

MIXED ANÆSTHESIA, WITH SPECIAL REFERENCE TO THE ADMINISTRATION OF HYOSCINE HYDROBROMATE BEFORE ETHER.

By E. A. ROBERTSON, M.D.,
SOUTH MILWAUKEE, WIS.

LATE ASSISTANT SURGEON, SAMARITAN HOSPITAL, MONTREAL, AND ASSISTANT GYNECOLOGIST, MONTREAL DISPENSARY.

For the purpose of producing a quieter anæsthesia, and in order to lessen the secretion of mucus in the air passages, and to diminish the disagreeable after-effects of anæsthetics, several drugs have been given by hypodermic injection, before the beginning of the inhalation. This method is known as mixed anæsthesia.

Morphine, alone or combined with atropine; atropine alone; chloral; and, lastly, hyoscine hydrobromate, as suggested by myself, have been used for this purpose.

A quarter of a grain of morphine hypodermically one hour before the commencement of the anæsthetic produces a state of calm at the time of inhalation which is highly desirable. The anæsthetic is taken more quietly, excitement is diminished and the secretion of mucus much lessened. The anæsthesia is maintained with a smaller quantity of the agent used and the muscular relaxation is complete.

It possesses the disadvantages, however, of intensifying the action of ether and chloroform, and of aggravating the nausea and vomiting afterward. In abdominal operations it locks up the bowels and makes distention greater and more difficult to relieve. Alarming respiratory depression, especially with chloroform, and prolonged stupor have been caused by it. Regnier and Lucas have observed a number of deaths which they attribute to it. Regnier states that morphine lessens the elimination of chloroform and favors accumulation, and in this way makes it more easy to give an overdose. In excitable and neurotic subjects, or in those with pulmonary or renal disease, whed a small amount of anæsthetic is desirable, it is of service.

Combined with atropine, the effect of morphine is more pronounced, especially in its action upon salivary and bronchial secretion, and at the same time atropine counterbalances the depressing influence of morphine on the respiration. On the other hand, the bad after-effects of morphine are not done away with. Atropine alone, acts mainly through its influence on the salivary and mucous glands. It prevents obstruction by fluid in the mouth and respiratory passages. However, it does not prevent excitement but even may increase it, and has no influence in lessening after-effects.

Chloral has been tried before ether, but produces most disagreeable symptoms after the withdrawal of the anæsthetic. It is a powerful depressant, and is dangerous, especially with chloroform, when collapse is apt to come suddenly.

A year ago, in considering the subject of mixed anæsthesia, it seemed to me that if some substance could be found which would accomplish all the good of morphine and atropine without their danger, and bad after-effects, a considerable gain would be accomplished in the art of producing general anæsthesia.

Something of this sort seemed especially desirable in the case of ether which, though by far the safest anæsthetic for long operations, is more difficult to administer satisfactorily than chloroform, and has more distressing sequelæ. I therefore decided to try hyoscine hydrobromate, and so far I have had extremely satisfactory results. I have taken accurate notes of all the cases in which I have given it, and, as I possess records of more than five hundred administrations of ether alone, with the Clover inhaler, I have been able to compare the two methods.

I purpose now to give an account of my cases, prefacing it with a short description of hyoscine hydrobromate as obtained from the literature.

According to Wood, hyoscine hydrobromate is the hydrobromate of an alkaloid obtained from the plant hyoscyamus niger, a member of the order *Solanaceæ*. The other members of the family used in medicine are: Atropa belladonna, Datura stramonium, Duboisia myoporoides, and Scopolia carniolica. From these plants are obtained the alkaloids, atropine, daturine, hyoscyamine, hyoscine, and scopolamine, which have all the same formula, but differ in molecular structure and physiological action.

It has been asserted that the hyoscine of commerce, which is a syrupy liquid, is obtained, as a rule, from scopoline and, therefore, is scopolamine. Hesse and Merck say that scopolamine consists of two bases, hyoscine and atropine, and as the action of the latter is unknown, it is important to see that the hyoscine used is made from Hyoscyamus niger.

In man hyoscine hydrobromate causes: (1) Dryness of the mouth and respiratory mucous membranes; (2) flushing of the face; (3) great drowsiness, deepening into sleep, and sometimes semi-delirious mutterings and dizziness; (4) diminished frequency of respiration; (5) diminished frequency of pulse rate; (6) as a rule dilatation of the pupils; (7) depression of the motor nervous mechanism.

It does not affect the sensory part of the nervous system, nor does it influence the secretion of the sweat glands as does atropine. On the circulation it has little effect beyond a slowing of the pulse rate.

Sohrt and Pavloff have studied the pharmacology of hyoscine chloride. They agree in the main. Sohrt found that the heart was quickened by paralysis of the cardioinhibitory apparatus, and did not observe changes in blood-pressure. In these conclusions he was supported by Wood. Pavloff found the heart slowed by stimulation of the cardio-inhibitory apparatus, and secondarily quickened by its paralysis. Blood-pressure he found first increased and then reduced to normal or below. The rise was due to stimulation of the whole vasomotor apparatus, especially the centers in the brain and cord; the fall to weakened muscular force of the heart. Sohrt says there is no effect on the respiration. Pavloff thinks that respiration is slowed by a depressant action on the respiratory center.

Both observers agree that hyoscine decreases salivary secretion, that it has no action on temperature or the reaction of the blood; that it diminishes the irritability of the brain, and to a small extent painful perceptions. It has no effect on tactile sensibility. It dilates the pupil slightly from stimulation of the sympathetic. It is very like atropine, except for the lowering of the irritability of the brain.

According to the latest edition of "Wood's Therapeutics," no fatal case of poisoning has been reported. I have been able to find, however, one case terminating fatally after an ordinary dose, and I have been told of another by the superintendent of a lunatic asylum. Several cases have been reported of alarming symptoms following comparatively small doses of the drug. It may be possible that certain individuals possess an idiosyncracy to hyoscine, as in the case of atropine.

In considering the reports of untoward symptoms caused by hyoscine, one must take into account the conditions under which the drug was given. As it

has mainly been used in cases of mania and in delirium tremens, and often following the administration of other powerful drugs, it is hardly possible in any case, to state that the symptoms following were due wholly to the action of hyoscine.

In one of the fatal cases which I have mentioned, the patient was suffering from typhoid fever, and the collapse following might have been produced by the weak state of the patient or by hemorrhage or perforation. In the other case, morphine and chloral had been given before the hyoscine, without effect, in a case of acute mania.

In 1,600 single administrations in an asylum in Austria no untoward symptoms were noted. One-quarter grain has been taken with no more disagreeable effect than prolonged sleep. On the whole, it is, I think, possible to say that given in doses of from $\frac{1}{120}$ to $\frac{1}{100}$ grain, the drug is perfectly safe in a subject not affected with delirium tremens, or when no other drug has preceded it.

Thomas Draper, Resident Medical Superintendent of District Asylum Enniscorthy, says of hyoscine (*British Medical Journal*, 1889), "It is a safe, certain, and rapid cerebral sedative, unattended in the vast majority of cases with any bad result." He has seen no unpleasant symptoms which have given any anxiety. I append the cases of poisoning which I have been able to collect:

R. A. Morton, Netherton, Ayr, reports a case.—Two drops of 1-per-cent. solution were put in each eye—$\frac{1}{75}$ grain. Five minutes after the patient complained of dizziness and lightness in the head. He staggered and had to be helped to bed. Complained of great dryness of mouth and throat, with thirst; giddiness became increased; senses became confused and speech was lost. Complete muscular relaxation and unconsciousness followed. Breathing was slow, face was flushed; pulse full and regular. Unconsciousness lasted four hours and was succeeded by semi-consciousness and delirium of a pleasant form for two hours, then calm, natural sleep for one and a half hours. The patient awoke and said she had not had such a good sleep for a long time. There were no evil after-effects.

Herbert Evans of Edinburgh reports a case of delirium tremens, in which 2 m. of 1-per-cent. solution were given, but had no effect. Eight hours after 3 m. by mouth were without action. In the evening morphine and chloral also had no result. Later 3 m., presumably of same strength but from another bottle, were given as a hypodermic. Following this the patient became rapidly comatose with dilated pupils, rapid pulse and congested face. Morphine was injected, then injections of pilocarpine of unknown amount every five minutes. The writer states that he probably gave gr. ii of nitrate of pilocarpine. The patient, wonderful to state, recovered.

S. W. Morton of Philadelphia reports a case in which $\frac{1}{75}$ grain was given to a medical man of 200 pounds, very irritable and susceptible, to relieve sleeplessness which had resisted all of the known hypnotics. No other drug had been given within forty-eight hours. The patient was in bed. In five minutes there was dryness of mouth, constant desire but inability to swallow; in a few minutes thickness of speech and complete paralysis of soft palate and upper lip. Pupils slightly dilated. Patient rose and staggered as one drunk. For ten minutes there was low muttering, then voice failed to a whisper; clinic convulsions and tetanic condition; opisthotonus; pupils widely dilated; pulse slow and full; respirations slow and deep and skin flushed. Movements soon gave way to complete relaxation, and in twenty-five to thirty minutes profound stupor with respirations full and stertorous and pulse slow and full. The stupor lasted six hours, when he arose with slight dizziness and difficulty in swallowing, and tendency in walking to go to the left, which persisted until the afternoon.

Joseph S. Gibb of Philadelphia reports a case: A man of fifty-eight was given $\frac{1}{75}$ grain by mistake. In forty-five minutes he was actively delirious. In a short time he could not recognize surroundings but would answer loudly when called. The pulse was full and regular; respirations diminished from eighteen to fourteen and became irregular. Pupils negative. Tongue and mouth dry; keenly sensible to pain. Delirium persisted in spite of morphine, all night, and full recovery was delayed to following evening.

William A. Carey, reports three cases. In his own case he took $\frac{1}{100}$ grain and repeated in two hours. There was dryness of the mouth, flushing, depression of muscular power, delirium, usual delusions, dilatation of pupil, and muscular tremors. All effects, except on pupil, passed off in thirty-six hours.

The second case was one of typhoid fever, $\frac{1}{60}$ grain was given. Half an hour after, mild delirium, widely dilated pupils, feeble fluttering pulse, imperfect articulation, cold extremities and cyanosis. Patient died. At the time it was thought to be perforation.

The third case was in a drunkard. All excitement was increased recovery.

In the *Australian Gazette*, 1888, Dr. Ralph Warran, reports a case: One-onehundredth grain, hypodermically, was given for the examination of a nervous woman. In ten minutes there was faintness, dryness of mouth, pupils widely dilated, pulse weak and rapid and skin cold and clammy. Ether and other stimulants and pilocarpine improved the condition. She could not be sent home, however, for eight hours.

From these reported cases it would appear that hyoscine is not a dangerous drug when given in an ordinary dose, though the last case points to the conclusion that some individuals may be very susceptible to the action of the drug, yet a high degree of hysteria may have been present.

I have given hyoscine hydrobromate so far, before fifty-seven operations; of these twenty-four were abdominal, ten were combined plastic and abdominal; nine plastic, two vaginal hysterectomies, one cauterization of cervix and vagina for cancer, one growth in the bladder, two applications to the bladder of strong nitrate of silver, and eight curettings.

All these operations were upon women, and in all the Clover inhaler and ether were used. One-onehundredth grain of hyoscine hydrobromate was injected in each case hypodermically one-half hour before the beginning of the ether inhalation. The effects of the injection observed clinically before the commencement of the ether were slight but constant.

In from three to ten minutes the mouth never failed to become dry, and thirst was almost always present. At the same time the pupils began to dilate, and continued in that condition until the ether was administered; at the same time they responded to the light reflex and accommodation was not lost. Within five minutes, as a rule, the patient began to feel drowsy. In some cases this drowsiness was pronounced, and in one case was deepened into sleep. In several cases drowsiness was not present at all. The face was quite normal in color in most of the cases, but in a few was flushed. There were no symptoms of excitement or delirium,

nor did the patients ever complain of dizziness or vertigo.

In the great majority of cases the patients did not exhibit as much anxiety as usual, and were generally calm and quiet at the commencement of the ether. The pulse, except in the case of one suffering from great weakness, was slow and full and regular, and the respirations were deep, quiet, and of normal rate.

The ether was inhaled freely and quietly and produced no secretion of mucus in the great majority of cases. Air was admitted with greater freedom than usual without producing any excitement, but preventing cyanosis and rigidity. Most of the patients passed quickly into the stage of surgical anæsthesia (though, as a rule, I do not hurry the administration), and in from two to fifteen minutes were ready for the operator. The anæsthesia was then maintained with a very small quantity of ether and a large amount of air for many hours. During this time the patient appeared as if in a calm sleep; the pupil was not always dilated and reacted to light.

The face was, as a rule, now flushed; the breathing quiet, slow and full and unobstructed by mucus, which was absent from the mouth and pharynx. The pulse was slower than usual in ether administration, but regular in volume and rhythm. There was a marked absence of vomiting during the administration of the ether. The recovery was, as a rule, more rapid than when ether alone was given, and in nearly 50 per cent. of the cases there was no after-vomiting at all, and in not one case was it very severe or prolonged. In most of the cases in which vomiting did occur, it came on before consciousness returned and was not remembered by the patient. In other cases it was absent at first and only occurred after the administration of calomel or salines.

During the first twelve hours following the end of the ether administration there was a tendency to sleep from time to time noticed. The dryness of the mouth persisted generally all through the operation, and for some hours afterward. The secretion of urine was not affected in any way, and in no case was albuminuria found after the operation when it was not present before.

No dangerous symptoms arose at any time which could be fairly attributed to the use of the hyoscine. Indeed, I have never had a set of cases of equal number in which the phenomena of anæsthesia were so slight and the course so uneventful.

The results in detail were as follows:

Fifty-seven Operations: 24 abdominal, 10 abdominal and plastic combined, 9 plastic, 2 vaginal hysterectomies, 1 cauterization of the vagina and cervix for cancer, 1 growth in bladder, 2 applications of strong nitrate of silver solution, 8 curettings.

All were in adult women, ranging in age from eighteen to seventy years. In all cases the Clover inhaler was used.

The total length of time occupied by the 57 operations, reckoning from the time of starting the ether to the time of the end of the surgical proceedings, was 129 hours and 12 minutes. The total quantity of ether consumed was, ℥ 370½; the average amount to the hour was ℥ 2.88. The average time taken to anæsthetize was 5½ minutes; the shortest time taken to produce full surgical anæsthesia was 2 minutes, and the longest time 15 minutes. The longest operation, from the start of anæsthesia to the close of the surgical proceedings, was 5 hours and 43 minutes; the shortest operation lasted 20 minutes.

Drowsiness was present in 38 cases. The pupils were dilated during the ether in 17 cases. In 50 cases the mouth and air passages were perfectly free from mucus. In 5 cases the mucus was very slight. In 2 cases, when the patient was removed from the bed to the table, some thin fluid was brought up from the stomach. In one of these coffee-ground material ran out of the mouth from the stomach when the patient was put into the Trendelenburg position. In one case there was much mucus and cyanosis for half an hour (case of abdominal hysterectomy).

In 55 cases there was absolute quiet during the administration. In 2 cases there was some struggling at the very commencement, before the patient had absorbed any ether. This was due to fright in very nervous patients, but as soon as regular inhalation began, calm succeeded.

In 28 cases there was vomiting after the operation, but in no case was it severe or prolonged. In 29 cases there was no vomiting whatever. Headache was markedly absent. The pulse rate ranged from 62 to 124 in the 57 operations, and the respirations from 20 to 52. The average pulse rate was 84; the average respirations 28.

In one case, in an elderly woman, there was a mitral regurgitant murmur, apex beat one inch outside the nipple line, swollen legs and scanty and albuminous urine. In this case, one of ovarian tumor, the operation lasted 2 hours and 17 minutes. The anæsthesia was perfectly satisfactory, no mucus, pulse regular, from 62 to 96, no vomiting after and good recovery, with no increase in albumin.

In another case there was an aortic systolic murmur. In this the anæsthetic was remarkably well taken, and the pulse and respirations were perfectly satisfactory during an operation which lasted 5 hours and 43 minutes.

In another case there was marked emphysema and bronchitis. The anæsthetic was taken beautifully, and there was no increase in the bronchitis.

In none of the cases was there any bronchitis following the ether or other respiratory disturbance.

In considering the action of ether we must remember that, as a general rule, it is by far the safest of the general anæsthetics for long operations. But, given in the ordinary way, whether by the open or closed methods, it has its limitations. Let us consider upon what bad effects these limitations depend. Ether is primarily a stimulant and a powerful one. It is an excitant, it produces salivation and secretion of mucus in the air passages and acts as an irritant to them. It interferes by this latter action with the proper aëration of the blood, and indirectly causes muscular rigidity. It raises blood-pressure greatly. It causes headache, nausea, and vomiting in a large percentage of cases, while the patient is recovering from its effects.

Hyoscine hydrobromate has a powerful action in counteracting these conditions. It acts as a cerebral sedative and renders the patient calm and free from excitement. It controls salivation and the secretion of mucus in the air passages, an action which, in my opinion, furnishes the best reason for its use. It prevents after sickness in a good large percentage of cases, and by slightly lowering blood-pressure and slowing the pulse, and by its power of lessening cyanosis, prevents dangerous cerebral congestion.

I wish to lay great stress upon the benefit which is derived from the property of hyoscine of stopping the secretion of mucus in the air passages.

Mucus obstructs respiration and causes cyanosis from the mechanical impediment which it offers to the free entrance of ether and air into the lungs. The swallowing and coughing caused by it may

compel the anæsthetist to stop the ether until the act of vomiting clears away the obstruction. Probyn Williams says, "An excessive secretion of mucus may be of such importance that it may necessitate a change of anæsthetic."

We are all familiar with the alarming picture which is presented by a patient during the administration of ether, with purple face, distended veins, rigid muscles, and labored respiration, with the mouth full of mucus, which is in vain swabbed out by the anæsthetist, until the act of vomiting comes to his relief and clears the air passages. This condition is highly dangerous in old subjects with weakened arteries, and kidneys, perhaps, somewhat the worse for wear.

Is it not reasonable to suppose that the presence of mucus in the trachea and bronchi, impregnated with the irritating ether vapor, may be a pregnant cause of cases of bronchitis and pneumonia which have been reported as following etherization?

Again, the vomiting which is caused during the recovery from ether may be partly central, but I believe, is mainly caused by the direct irritation of the large amount of ether-impregnated fluid swallowed, and secreted from the stomach and duodenum, which acts after the inhalation has stopped. Many a time I have seen a patient in the middle of an operation, when put in the extreme Trendelenburg position, bring up a pint of evil-smelling liquid from the stomach. May we not well suppose that the presence of such irritating material in the stomach may, when reflex action returns, cause the intense nausea and vomiting which so often follows ether? In the case of an abdominal operation this vomiting may lead to disastrous consequences.

I maintain, then, that hyoscine hydrobromate, if it proves to be without danger, is a valuable aid in the administration of ether. No doubt some day there will be found some agent possessing the same action upon the sensory nervous system that curare does upon the motor part, which will be given hypodermically, in a definite safe dose, and which will fulfil all the requirements of an ideal anæsthetic; until this agent is found, however, we should seek, in every way possible, to make the administration of the anæsthetic agents we have, as agreeable and safe as possible and it is with the belief that hyoscine hydrobromate, in conjunction with ether, offers us great assistance in attaining those ends, that I bring it to the notice of the medical profession.

I am indebted to Dr. William Gardner of Montreal, who allowed me to try the hyoscine in his hospital.

Some Simple Therapeutic Experiments.—W. Essex Wynter mentions a number of expedients and remedies which may with benefit take the place of internal medication in certain cases. Cradling, the application of cold, of heat, dry or moist, the comfortable arrangement of mattresses, position, mechanical support for the abdomen, are some of the subjects considered. As a remedy for vomiting he especially recommends the continuous or repeated inhalation of oxygen. In the various forms of persistent vomiting—functional, reflex and organic—no other means has proved so uniformly effectual. It is perfectly harmless under all conditions, it requires no effort on the part of the patient beyond that of ordinary respiration, and involves no suffering or after-effects of a disagreeable character. Being administered by the lungs, it not only acts independently of vomiting, which may continue for a time, but is peculiarly serviceable in such cases as those of gastric neurosis, irritability, inflammation, or ulcer, in which it is undesirable or useless to introduce anything into the stomach, or after laparotomy, when, in addition to this, retching is particularly obnoxious.—*Treatment*

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By FLOYD S. CLARKE.
SIOUX CITY, IOWA.

It is only by exercising the most thorough care and attention to every minute detail of diagnosis, that we can hope for success in the early recognition of this affection. The great majority of our cases of phthisis do not come to us until the disease is well established. Comparatively few patients come to us in the early stages. We are all aware of the necessity of an early diagnosis, for so much of our ultimate success in the cure depends upon our forming a conclusion early.

How often it is that a diagnosis of phthisis is made when we least suspect the disease. The patient will often complain of some obscure symptom or symptoms, and careful questions will elicit no no fact which would lead one to anticipate phthisis; but, on examining his lungs, we find unmistakable evidences of disease.

Undoubtedly, heredity plays an important rôle in the etiology. That it is not as important an etiological factor as was supposed some years ago, is admitted by most clinicians. The personal habits and environments of the patient should be inquired into, the amount of exercise taken each day, his vocation in life; whether in-doors during the day, where he can obtain a minimum amount of fresh air and sunlight, or whether his occupation is such that will enable him to obtain an abundance of these materials. The weight of the individual should be carefully considered. A pair of scales should be in every well-equipped physician's office and the weight estimated frequently. The condition of the pulse is of great diagnostic value, and frequent daily countings should be taken, the same being noted on a chart if possible. Usually the pulse of early phthisis will vary from ninety to a hundred and ten beats per minute, but it may be less or even more. It is usually a high-speed pulse; is quick, and of little volume. This high-speed pulse is especially present in the early stages, and should have considerable weight in the final summing up of diagnostic points.

The temperature should be carefully taken at least three times daily. Usually an evening rise, from 99° to 101° F., will be present. This, however, is not constant, and occasionally the temperature will be subnormal.

Digestive disturbances are often the first symptom complained of in early cases. Too much stress cannot be placed upon the importance of this part of the diagnosis. Of course, every case of early phthisis does not have indigestion, so called, but it is of great weight and should always call for further questioning and examination. Chest pains are misleading and not of much significance; occasionally, they occur, particularly in the upper portions of the chest.

The presence of a constant harrassing cough is not of much importance unless accompanied by other objective or subjective symptoms. The absence of a cough does not necessarily mean that the patient has not tuberculosis. It is not uncommon to find individuals with the physical signs of phthisis without cough. The presence or absence of expectoration does not mean much in the early cases.

The finding of tubercle bacilli in the sputum is confirmatory evidence of the presence of the disease. Their absence throughout the early stages is not uncommon. They should be found in large numbers, say eight or ten in a field, in order to be convincing. The finding of two or three bacilli on a slide is not enough to establish the diagnosis, unless other physical signs and symptoms are present. It

is rather common to find one or two bacilli on a stained specimen without the disease being present. It is often found in places where a number of tuberculous patients are housed, that the sputum of the healthy attendant contains a few bacilli.

The test of tuberculin has been lauded by some authors and condemned by others. I do not believe it should be employed as a means of diagnosis in these early cases. The reaction following the injection is not always to be depended upon, and the method is therefore decidedly unreliable.

Fistula in ano may be associated with diseased apices. The presence of this condition, in a given case, should necessitate a careful physical examination.

I now come to the physical signs obtained in a typical case. These may not be found on the first few examinations. It is important that we make several physical examinations on different occasions before definitely giving an opinion in a case. There may be appreciative dulness over an apex on one examination which is not present on a subsequent one. We may think we hear the roughened inspiration at one time and not hear it at another. I cannot emphasize too strongly the great importance of repeated physical examinations.

Inspection of the chest may be absolutely negative. Occasionally we will notice diminished expansion on the affected side; particularly if much consolidation be present. We read a great deal about the so-called phthisical chest. It is just as common to find phthisis present in the well-formed chest as it is to find it in the flat-chested individual.

The *x*-ray will often give a shadow over a greatly or slightly diseased apex, but it cannot always be depended upon. When the shadow is present on the skiagraph, it is good confirmatory evidence of the disease. When absent, it does not rule it out.

The evidence obtained by palpation depends, of course, upon the amount of consolidation present. Usually we obtain increased vocal fremitus on the affected side. The correct way of obtaining this increase is not by placing both hands on the chest at the same time, but first placing one hand on one side of the chest and asking the patient to count; then taking that hand from the chest, and placing the other hand on the other side of the chest, the patient being told to count again. It will be found that vocal fremitus is much more easily appreciated by this method.

Percussion gives impaired resonance amounting sometimes to dulness over the affected area. The percussion note cannot be described and must be heard in order to be appreciated. Sometimes it can be better obtained by instructing the patient to hold his breath at the end of expiration.

On auscultation is heard the typical, rather short, loud, roughened inspiratory, vesicular murmur with the prolonged, blowing, expiratory, bronchial effort. This is the pathognomonic sign of beginning tuberculosis, and is the most constant of all physical signs. It can be elicited only by careful auscultation and comparison with the normal breath sounds. In the very early stages the breath sounds may be simply somewhat rougher than normal. If this sign is present, it should excite suspicion in the mind of the physician and call for further examination. Another almost constant ausculatory sign is the crepitant râle heard at the end of inspiration. These sound exactly like the rubbing together of several hairs, and can often be obtained by telling the patient to cough and afterward taking a deep inspiration.

I have herein tried to give the physical signs of *early* cases in which very little, if any, consolidation is present in the affected lung. As the disease advances, other physical signs will be obtained and these we all know.

A brief summary of the points I desire to emphasize may be in order here, they are: (1) An increased pulse rate; (2) Gradual loss of weight and strength without obvious cause; (3) An evening rise of temperature; (4) Digestive disturbances, which are often present early and should be inquired into more carefully; (5) The finding of numerous tubercle bacilli in the sputum; (6) The bronchovesicular, or probably better, as some authors term it, the vesiculobronchial, breathing; (7) The small crepitant râles heard at the end of inspiration; (8) The necessity of repeated physical examinations in order that we may reach definite conclusions; (9) The importance of keeping a daily record of the pulse and temperature.

A SIMPLE AND ACCURATE METHOD OF EXAMINING THE STOOLS FOR GALLSTONES AND OTHER SOLID BODIES.

By HOWARD LILIENTHAL, M.D.,
NEW YORK.
ATTENDING SURGEON TO MT. SINAI HOSPITAL.

STRAINING a foul stool by the methods ordinarily in use is a task so distasteful to most persons that unless it is performed by the physician himself it is apt to be shirked or carried out in a careless and inefficient manner. Yet the conscientious search for foreign bodies in the fæces may be of enormous importance in arriving at a diagnosis. For a number of years I have employed a method which is far less disgusting than any other with which I am acquainted, while it is so accurate that even the smallest solid particles cannot be overlooked. The examination is easily made by the nurse or even by the patient.

Take a loop of telegraph wire a few inches greater in diameter than the entire top of the closet seat, and fasten to this a bag of at least two thicknesses of dressing gauze or mosquito netting. The bag may be sewn to the wire or simply held by safety pins, but it should be made very full, so that when the hoop is in place the wire shall be well below the level of the seat and out of the way, while the bag shall hang down into the water at the bottom of the bowl. If the patient is not confined to bed he defecates into the closet, and then simply opens the water valve often enough to wash away all soluble and amorphous matter, while solid bodies will be left in the bag. If the patient is confined to bed, the stool must, of course, be carried to the closet. It is best not to put paper in with the stool. In rural districts where there may be no plumbing the same procedure may be followed, except that the water must be carried to the privy and poured through by hand.

The principal advantage of this method, especially in city practice, is that the patient himself may be trusted to make an absolutely accurate examination. I have been able to confirm a diagnosis of cholelithiasis from tiny faceted stones considerably smaller than a mustard seed, which were discovered in the stools by the patient.

766 MADISON AVENUE.

Cystic Tumors.—A. G. Eliss says that, in view of the possible malignant degeneration of cystic tumors of the breast, as a rule, it is a wise policy to remove breast tumors on suspicion.—*The Medical and Surgical Monitor.*

New York, January 9, 1904.

HOSPITALS IN SORE STRAITS FOR FUNDS.

IN the current number of *Charities*, the official organ of the Charity Organization Society, Mr. Frank Tucker shows that a score of private hospitals in this city are operated under conditions which result in a total annual deficit of $450,000. A manager of one of these institutions is quoted as saying: "We are pretty near the breaking point. The time has come when some of those who have been carrying the load will have to step from under." This is certainly a very significant statement and carries with it a serious reflection on the present methods of hospital management. Either the public does not properly appreciate the efforts of certain philanthropists or many of the institutions fall far short of their aims. From a purely business aspect their enterprises are failures. Paradoxical as it may appear, even the game of charity is a losing one.

A table made up from the annual reports of the institutions for the past year shows that St. Luke's Hospital ran behind $27,566, Roosevelt $6,000, the Presbyterian $80,229, the Woman's Hospital $10,700, the Flower Hospital $8,224, the Ruptured and Crippled $55,675, the Post-Graduate $44,103, the Lying-in $88,477, and Mt. Sinai $58,160. These are startling figures to the uninitiated, although there may be some reasonable explanations for their computation. They prove quite conclusively that ordinary voluntary benefactions are entirely inadequate to meet necessary expenses. Subscriptions are intermittent and irregular, while running expenses are unalterably progressive. The endowment plan is the only safe one.

The modern hospital is a very costly establishment, even when managed on most economical principles. The trouble is that few of the projectors take the truth to heart until it is too late.

A magnificently imposing building is the first consideration, and too little thought is given to its subsequent maintenance. The main question of its actual need is left to chance proof. There is no doubt that too much money has been spent in brick and mortar, and this, with heavy mortgages on real estate, contribute largely to the deficit. This, too, in spite of the fact that most if not all the hospitals named not only receive pay from patients when such is possible, but let expensive suites to wealthy patrons. The Presbyterian Hospital is conspicuous in this regard with a debit account of over $80,000, while Roosevelt, with even more advantages as a hotel-hospital, also falls short of making its expenses.

It might be argued, perhaps, that the hospital market is a trifle over-stocked and that there would be a better chance for the few than the many. From the purely economic side this would appear to be evident enough, as on general principles a business that cannot be made to succeed should not exist.

The responsibility of conducting such institutions should not fall on the few men having them directly in charge, and it is only a question of time when some of those who are carrying the load should "step from under." But hospitals multiply notwithstanding, whether they can fulfil their ultimate purposes or not. Most of them do not succeed, either as business ventures or as purely charitable necessities. The consequence is that the number of free beds is disproportionately small to those with board in private rooms, and the institution must be run on the hospital-hotel basis. Even excluding the cost of the building, there are no known methods outside of endowment funds that will make its success possible. The lying-in hospital donated by Mr. Pierpont Morgan has a deficit of $84,000 and more. The white elephant is compelled to forage on outside resources to live, and at present rates will eventually devour itself. There may be some truth, after all, in the statement that we have too many of such charities and that the time has come for some of the managers "to step from under" their assumed responsibilities. In any other undertaking the question could be easily settled. One trouble rests in the forced mixture of charity with pecuniary tribute. The model hospital should be free to every poor and needy person without distinction. Otherwise sympathy lags and donations are not freely offered. In point of fact, the municipality should take care of all the poor of the community and make outside and voluntary aid unnecessary. Hence, the proposition to create a ten-million dollar fund for the purpose is sensible enough on common grounds, but thoroughly impracticable from the standpoint of private control of the donation. By the recent appropriation of millions of dollars for the erection of a new Bellevue and other public hospitals the city government is trying to solve the problem of care for the sick in its own practical and business-like way. Perhaps this is the one and only method of settling the grave question at issue. We could then divide the private hospitals into two classes—one the endowed institutions that could afford to treat every worthy applicant free of charge; the other that would be managed as any other hotel for the mere profits that might accrue. There would then be no question which deserved voluntary contributions and which could use them to the best advantage for the really needy applicants. As it is, the public is being led to believe that each private corporation managed on the double basis of charity and pecuniary gain should be able to take care of itself. All this by no means implies that the hospitals have not done noble work, but that, by an inordinate zeal in aiming at impossibilities, they have defeated the main objects of their existence.

Pilocarpine is a specific for jaundice, and relieves all forms of itching, with the exception of that due to hepatic cancer. **Locomotor ataxia** and **tetanus** have been repeatedly reported cured by the administration of large doses of pilocarpine. The dose is gr. $\frac{1}{67}$ to $\frac{1}{23}$ every five minutes till sweating or salivation begins to appear.—*The Southern Clinic.*

THE LESSONS OF THE CHICAGO THEATRE FIRE.

THE lamentable loss of life in the Chicago theatre fire has provoked much discussion as to the probability of preventing similar disasters. As is always the case, many things have been discovered to have been left undone which should have been done. The building was claimed to be fire-proof in its construction, but contained all the inflammable material necessary to make it a veritable furnace when the fire gained its headway.

There was a culpable lack of promptness in tackling the fire at its inception, and, worst of all, the protecting curtain was caught when half-way down. Thus the body of the theatre became a veritable flue for the stage blaze. The dreadful result was what might have been expected when passageways became quickly jammed and other means of exit likewise choked.

It might have been possible to have lessened the loss of life by maintaining some order in the frantic audience, thus allowing ready escape, but such conditions are never present under the circumstances.

In the face of personal peril crowd panic is inevitable. Once under way its force accumulates in proportion to numbers. It is active and retroactive in its effects and gains fury with its duration. Each individual becomes a virtual maniac and the primitive instinct of self-preservation is paramount.

Deliberation and calm reasoning are always at a discount. This is abundantly proved by the fact that the crush and struggle are always in the direction of the greatest danger. Where the fight is thickest there is the greatest number of combatants. It has been well said that virtually the same thing would occur in an open plain if the requisite incentives were prevailing. A notable example of this was furnished at Hodynsky in Russia in 1896, when hundreds were killed while ready escape was available in every direction save the one that was so madly taken. In the *Bazar de Charité* in Paris the year following the same drama was rehearsed, and so it will be probably to the end of time, so long as crowd panic takes its awful opportunity. To control it is as much a psychological impossibility as it would be to calm the delirium of terror in a single individual in the extreme of peril, and even more so when the conditions for its multiplication are in full sway.

What mercy there is in the after-contemplation of the calamity is that the agony is so soon over. In the case of the Chicago fire it is quite evident that those who were not crushed to death at the start were quickly smothered by the smoke and the poisonous gases of combustion. Notably these products comprise carbonic oxide, sulphuretted hydrogen, chlorine, and the various ammonia compounds. These have very direct toxic effects upon the respiratory center and produce asphyxia with great rapidity.

The main question turns upon the chances of reducing fire accidents to the minimum. Various devices have been suggested to this end, the principal of which is the asbestos curtain that can be lowered between the flames on the stage and the audience.

After the disastrous Brooklyn Theater fire in December, 1876, this subject was very fully discussed, particularly by the MEDICAL RECORD, and ample arguments were offered to prove the utility of the measure; at the same time it was suggested that all inflammatory stage fixtures should be treated with alum solutions, and also that heavy ornamental box draperies should be discarded.

For a time every effort was made to cater to public sentiment, but too soon promises were forgotten and the old-time methods were in vogue again. Even in regard to the asbestos curtain, now a part of the fixture of the principal theaters, it has lately been discovered that their mechanical efficiency is not by any means what it should be. In Chicago, where the lesson of neglect of precautions brings the object lesson home to the people, it has been found necessary to declare its theaters absolutely unsafe in this regard. This, too, at a time when theater managers are volunteering so many positive statements regarding the impossibilities of accidents in their respective establishments.

Not long ago, in this city, when the fire commissioner pointed out the danger of crowded aisles, there was enough contrary influence among the theaters to set his warnings at naught and defeat his purpose of better protection for the public. Now, however, that the general subject again claims serious discussion, there may yet be hope that some radical and efficient protection may be afforded along these and other lines. In any event, the public for a long time to come will continue to be nervous over all pyrotechnic displays on the stage, and be duly apprehensive of unprotected lights and open imitation fires amid the scenery. Even the concealed electric wire may, in view of the last calamity, carry with it more than an ordinary dread.

SPECIALIZATION VERSUS SYNTHESIS.

SPECIALIZATION has, in the last half century, reached the highest development yet attained. Consequently workers in special fields were never so abundant as to-day. It is not difficult to understand why this has been so. This era of specialization was preceded by a period of tremendous growth in what may be called the fundamental sciences. Pathways almost without number were opened to new fields of investigation. The fundamental sciences, themselves, became, so to speak, specialized. The development of these special departments has in our time assumed large proportions. Increased knowledge shows that the various sciences do not stand side by side, but that to a certain extent they include one another. They overlap on their border lines. The solved problems of one are the primary factors of another. There are many synthetic relations which bind them firmly together. Specialization has led to synthesis. The wider the horizon of a scientific worker the more evident does this fact become. Professor Ostwald, at the dedication of the Rudolf Spreckel's Physiological Laboratory of the University of California, August 20, 1903, considers these synthetic tendencies in modern scientific thought. His address was upon the relation of biology to the neighboring sciences—notably physics and chemistry. As the professor expresses it, "the direction of the wind upon the sea of sciences" cannot be better illustrated than by considering the circumstances which surround his address. Here was a man invited to make the dedicatory oration at the opening of a biological laboratory who was

not only not a biologist, but was especially invited as the representative of a sister science. Furthermore, the man himself is the product of the synthesis of two neighboring sciences—physics and chemistry. Most curious of all, his address contains no word of physics and chemistry, but rather thoughts which concern the triad—physics, chemistry, biology.

Upon reflection it is evident that synthetic factors are not wanting in the various divisions of medicine. There never was a time in the history of medicine when its various departments were so dependent one upon the other as to-day. Without doubt this has been brought about by the great increase of knowledge in the special branches of our science. In considering this thought of synthesis in its application to medicine, however, certain truisms must be held clearly in view. Synthesis does not mean the abolition of workers in separate fields. It does mean the utilization by the workers in one field of the knowledge obtained in another. As the production of the physiological chemist has not done away with the necessity of the physiologist and chemist, nor the advent of the biologist with the usefulness of the histologist, bacteriologist or anatomist, so the coming of the physician thoroughly equipped in all branches of his profession will not occasion the withdrawal of the specialist in medicine. Synthesis, which is now manifest in the various departments of medicine and which will be more and more in evidence as time advances, threatens not, therefore, the individuality of him who would devote his life's work to one of these many subdivisions. This fact, although it insures his stability, increases the number of his requirements. As the biologist and physiological chemist must possess an accurate knowledge of their allied sciences, so the specialist in medicine must bring himself into intimate touch with the advances in all departments of medicine. These he must ever be able to utilize. This thought is not new, but it needs constant emphasis. This task is not as impossible of accomplishment as it at first appears. Many have watched the growth of the special fields of medicine with something akin to alarm. It has seemed as though the time were approaching when the specialist in medicine would no longer be able to prepare himself with a general medical training. So multiple would become the knowledge in any given field that its acquirement alone would be all that one man could successfully accomplish. This time, however, is destined never to appear. The development of any branch of science is always toward final simplicity. Increased knowledge always leads to simplicity of thought; increased facts to simplicity of ideas. The great masters in any field are always preëminent for the simplicity of their deductions. The time is therefore approaching when the acquirement of knowledge in the various departments of medicine will be easier than ever before. This statement will undoubtedly be strongly contested, but its truth cannot be shaken. It is founded on the history of scientific development. For the general practitioner also these synthetic tendencies of the medical sciences are full of hope. It has appeared to some as though the era of the general practitioner were drawing to a close. Such is, however, by no means the case. If there were no other reason for his continued existence, these synthetic factors assure his permanent position. The enlargement of his knowledge while not endangering the sphere of the specialist will bring to his aid a multitude of agencies which are as yet but little dreamed of. The watchword of medical advance to-day is combination. Only in this way is the solution of the great problems which confront us possible. The MEDICAL RECORD has not failed to appreciate this necessity nor to emphasize it as occasion has required. The innovation of synthesis in the various departments of medicine is, therefore, an event in which everybody may rejoice and which no one need regret.

MALARIA WHERE ANOPHELES IS USUALLY ABSENT.

The above title suggests a difficulty for the theory of the exclusive rôle of mosquitos in the transmission of malaria, and one which has been often presented. Indeed, in some cases, this difficulty has seemed so formidable that disbelief in the agency of Anopheles as a carrier of the infection has been boldly professed. In the *Journal of Hygiene* for October, Dr. John Cropper says that whereas last year in an article in that Journal he stated that though he had resided in Acre, Palestine, he had never been able to find a single Anopheles, this year his successor, Dr. Gould, having under his care two native boys with malaria, found Anopheles in their room. It is uncertain where they were bred, but the previous winter was exceptionally wet, the water coming to within half a mile of the town where malaria is comparatively rare, though common enough a mile away. At Shefa Amr, three hours from Acre, situated on low chalk hills which rise well above the plain and are remote from running water, two English ladies had malaria, and though no adult Anopheles were found, the larvæ were discovered in an open cistern. At Nablous, also, Dr. Gould found Anopheles larvæ in a shallow cistern which supplied water to the parsonage, and this year, without special apparatus, Cropper found nine Anopheles larvæ among a great many Culex and Stegomyia fasciata larvæ; and more recently two Anopheles larvæ have been found with many Culex larvæ at the new hospital. Though considering the great numbers of the patients, malaria is very infrequent, it is, nevertheless, quite well known in the town, and among the English ladies at the Mission a few yards away a few cases have occurred. Within four hours of Nablous is the Jordan valley, notorious for its unhealthiness, and within nine hours is Beisân, than which few places are more unhealthy. From both of these localities patients and visitors come to Nablous, and thus the stock of malarial parasites, which otherwise would become exhausted, is renewed. So it is probably with most, if not all, the places in the tropics which are not essentially malarious; that is, where the Anopheles does not occur abundantly. On the whole, therefore, Cropper's contribution tends to raise the question whether with more careful search Anopheles may not in future be found more and more frequently in places where its absence has hitherto been accepted.

FOOD ADULTERATION IN GREAT BRITAIN.

A commission has recently been sitting to inquire into food adulteration in Great Britain, and especially with regard to arsenical poisoning. The commission handed in its report a short time ago, and its most salient features are published in the *British Medical Journal*, December 19. The report concluded that the existing machinery of public health administration provides little if any system of official control over the proceedings of manufac-

turers. These were the recommendations made by the commission as to improvements in official control over purity of food: (*a*) Necessity for more extended administration by the Local Government Board. (*b*) Necessity for official standards. The commission recommend under (*a*) that a scientific experimental officer should be appointed, with suitable laboratory provision, with the duty of advising the Local Government Board on questions affecting the manufacture or sale of foods liable to be injurious to health or liable to valueless adulteration. This officer or his assistants should have the duty and power of making investigations and collecting information with regard to food products manufactured at home or imported from abroad, with a view to furnishing local authorities and their officers with authoritative information and advice as to the lines in which the sale of food and drugs acts may be administered to much better public advantage than is at present the case. With regard to (*b*) the commission endorses the recommendations of the Select Commission on Food Products Adulteration, 1896, and the Commission on Preservation and Coloring Matters in Food, 1901, that a scientific "Board of Reference" should be set up to deal with the question of "standards" required for the purpose of the sale of food and drugs acts. The commission further recommends that the sale of food and drugs acts should be amended so as to permit of manufacturers or intermediate vendors being attached to the prosecution. It also recommends that, with suitable safeguards, the powers of a medical officer of health to obtain the condemnation of unsound food should be extended, so as to enable him to "lay embargo" on the sale of suspected articles pending an official examination or analysis.

Adulteration of food is by no means confined to England, but is practised to a greater or less extent in all civilized countries. In the United States the custom of adding foreign substances to articles of diet—with the view chiefly of preserving them—is stated to be widespread. The MEDICAL RECORD has always made a point of strongly inveighing against and denouncing the practice. It has been urged that some of the added substances are harmless, although this has never been definitely proved. It is far more likely that every preservative detracts somewhat from the nutritive value of food. The public has, at least, the right to know what it eats, and when a food is bought purporting to be so and so, a distinct injury is done to the buyer if such be not the case. In those instances in which so-called harmless preservatives are used, the manufacturer should be compelled to advertise the fact by a label attached to the receptacle containing the mixture. There is room for sweeping reforms so far as adulteration of food is concerned in almost all civilized countries, and in the United States it is a matter that needs prompt attention.

SLEEPING SICKNESS.

At a meeting of the British Epidemiological Society, held on December 11, a paper on "Sleeping Sickness" was read by Dr. Louis Sambon. He expressed his belief that a trypanosoma was the cause of the disease, and that the species of tsetse-fly known as glossina palpalis played the part of alternative host. Dr. Sambon severely criticised the manner in which the experiments of the British commissioners were carried out at Entebbe, and said that these experiments would have to be repeated in a thoroughly scientific manner ere the question of the etiology of sleeping sickness could be said to be definitely determined.

The most interesting speech made at the meeting was that delivered by Sir Patrick Manson in the discussion which followed the reading of Dr. Sambon's paper. The speaker made some timely remarks on the question of priority in scientific discoveries. He said he was "especially pleased with that part of Dr. Sambon's paper in which he expressed the hope that questions of priority would not occupy the meeting. They were always thorny subjects and they led to a good deal of bad feeling, and, so far as his experience extended, never to any general profit. Sometimes on a Sunday he had an opportunity of contemplating the manners and customs of the fowl community, and his observations were generally taken between the morning meal and the afternoon meal when the fowls had picked up the last grain of maize, and apparently had no chance of getting more food. But even in the community of fowls of that description some enterprising bird would wander from its fellows, and by dint of perseverance would sometimes pick up a lob-worm in some corner of its habitation. Almost before one had observed the fact that this fowl had made the discovery, one also observed that this fortunate fowl was beset by numerous other fowls who rushed in to share the profit. As a result the first fowl was very quickly deprived of its morsel, and the second fowl succeeded in taking a little bit, and the third, and the fourth, and the fifth, until after a time it was found that the discovery had become the general property of the community, with the result that the owner of the fowls, in the long run, benefited by getting a more wholesome and nutritious egg in the morning. He believed that this was a fair simile as to what happened in the field of discovery. One man got hold of a lob-worm, a hundred men could extract part of the *éclat* perhaps, but in the end the whole world benefited by the discovery."

Sir Patrick Manson reviewed the investigations he made some years ago into the etiology of sleeping sickness, which made him almost decide that filaria perstans was the cause. Now he was very glad to disallow any connection between the filaria perstans and sleeping sickness. But as regarded the connection of the trypanosoma Gambiense with sleeping sickness, he should still bear in mind his experience as regards filaria perstans. His belief was that sleeping sickness was caused by trypanosoma Gambiense, but he could not say that it had been proved. Manson also did not think that Bruce's experiments were conclusive.

Prof. Ray Lankester also took part in the discussion, and deprecated the present-day custom of jumping too quickly at conclusions when making investigations into the origin of little known diseases. This hasty action is undoubtedly due to the fear of the investigator that if he does not immediately make known any discovery he may have made, he will be forestalled by some other man who is engaged in the same studies. Healthy emulation is good, but premature announcements of scientific discoveries do harm. The advice of Sir Patrick Manson, to be thoroughly sure of the ground before publishing as facts what are really little more than theories, might be taken to heart by investigators the world over.

DIET OF THE POORER CLASSES.

The proper feeding of children is one of the most important factors in building up a good sound constitution, and much of the loudly proclaimed race degeneration among civilized nations must be laid to injudicious diet. This is especially the case with the urban population. In Great Britain the defective physique of the town-dwellers is arousing wide-

spread attention, and various are the methods suggested to remedy the evil. In the *British Medical Journal*, for the past few weeks, a series of articles have appeared treating of the subject of race degeneration. The issue of that journal for December 5 deals with the diet of the poorer classes, and numerous quotations are made from a work recently published concerning the food of the laboring population of Edinburgh, by Drs. Noel Paton, J. Cranford Dunlop, and Miss E. M. Inglis. In the work referred to, the following postulates are laid down: "Since food is the sole source of the energy required (*a*) for building up the body (*b*), doing work, and (*c*) maintaining the temperature it is obvious that the working capacity and well-being of a community must be largely influenced by the food supply of the individuals. (*a*) Without an adequate supply of food, proper growth and development of the body are impossible, and not only is the work capacity of the individual diminished, but a predisposition to disease is induced. (*b*) . . . The working capacity of a man is conditioned by the amount of food he consumes and uses. . . . Food may be consumed by a man and no proportionate amount of work be produced. Thus an insufficient supply of food diminishes the work-doing power of the body in two ways: First, by preventing the full development of muscle, the great energy liberating tissue and, secondly, by not affording the potential energy for the work to be done. (*c*) Lastly, a sufficient diet is essential for the maintenance of the bodily heat." The authors then proceed to analyze the ordinary every-day diet of a number of laborers, showing that as a rule the composition of the foodstuffs used by the working classes are, on the whole, badly balanced and unsuitable. To improve the dietary of the laboring classes, the following principles should be instilled into them: (1) That a diet of tea and bread, or of tea, bread, and butter is faulty. (2) That the faults of the tea-and-bread diet can be corrected by the free use of meat, eggs, and other animal food, but that this mode of correction is expensive. (3) That the faults can also be corrected by the free use of oatmeal with milk, or of peas and beans without extra cost. (4) That to correct the faults of a tea-and-bread diet either money spent on animal food or labor spent on cooking is necessary. If they have not the money they must give labor necessary to the proper cooking of more nutritive foods. Of course, as in every other partial inquiry, it is difficult to come to a just conclusion as regards the feeding of the whole of Great Britain. Still a number of towns are included in this inquiry, and it may safely be concluded that the British urban laborer and his family have, as a general rule, enough money to spend upon food. But what is far more certain is that the vast majority of laboring men's wives have not the remotest idea of the relative properties of certain foods, as compared with those of others, nor of their relative price.

If this be the state of affairs with respect to the urban poor population of Great Britain, what of the same class in the United States? It is true that laboring men in the cities here earn a bigger wage than in the United Kingdom, but do they on the whole spend this money to better advantage in the matter of food? The native Americans, the Germans, and some of the Irish probably do expend a part of their earnings in food good in quantity and quality, but the Italians, Russians, and those from other European countries exist upon a diet which is both sparse and deficient in nutritive properties. As for the cooking of food, it is doubtful if the majority of working women on this side are not as ignorant of the art as are their sisters in Great Britain. A lesson might be learned in this connection from the peasantry of France, and to a lesser extent from those of Germany, who are extremely poor yet know how to choose and cook food judiciously and well. The question of good food is a peramount one in all that concerns a nation's prosperity. To raise a race physically and mentally sound, the children must be well fed, and in order to bring about this result the women of the poorer classes—especially in towns—must possess the knowledge of selecting suitable food and of cooking it in a proper manner. There is a wide field in the United States in which to impart this knowledge.

Functional Albuminuria.

This affection, sometimes termed intermittent, remittent, orthostatic, postural, and cyclic albuminuria, was the subject of discussion at the meeting of the Medical Society of London, held on December 14, last. The president of the society opened the discussion. In the course of his remarks he said that some physicians, including the late Sir George Johnson and Dr. Clement Dukes, considered that albuminuria was always pathological, and that the term "functional" was hardly justifiable. Its characteristic feature was that albumin was absent on rising in the morning, but appeared after breakfast. In the later part of the day it might again be absent. The effect of meals on albumin varied. In some of the so-called cases of functional albuminuria the amount of albumin was usually not influenced by diet, but in other cases the urine lost all trace of albumin under the influence of exclusive milk diet, and again became albuminous after a meal of solid food. On the other hand there was another class of cases in which exercise, and even the erect position of the body had more influence than food in the production of albumin. Functional albuminuria might occur at any age but it was most frequently met with at the period of adolescence.

Dr. Rose Bradford defined functional albuminuria as the occurrence of albuminuria in the apparently healthy. He then discussed as possible causes of the condition latent renal disease of an organic character, the subsidence or onset of renal disease and accidental albumin due to spermatorrhœa, or the presence of a discharge such as gleet. It might also be associated with diet, posture, exercise, fatigue, or bathing. Posture was the most important of these. The only clearly established pathological cause of albumin was some toxic agent—metallic poisons, ptomains, and bacterial toxins, substances present in the blood of all animas. But these were obviously absent in most cases of functional albuminuria. Reflex vasomotor mechanisms of a complex character were called into play when the body assumed the upright position. Posture was possibly the main cause of functional albuminuria.

Dr. Pavy said he could not regard functional albuminuria as an incipient stage of organic renal disease. He had watched cases for upward of fifteen years. Posture was a prominent factor in causation of this condition. Diet, in his opinion, did not play an important part; excessive exercise, however, was important, as was over brain work. An unstable vascular system was often present in such cases, and fully explained the occurrence of functional albuminuria. Mr. H. G. Armstrong said he had studied the condition during twenty years at Wellington College. He would divide functional albuminuria into three varieties: (1) Occasional, which was an extremely frequent condition; (2)

Intermittent, which occurred in from 10 to 15 per cent. of the boys; and (3) permanent, of which kind he could only remember about six cases.

Functional albuminuria is one of the most common affections known, and it is somewhat curious that it has not as yet been definitely decided as to whether the condition is pathological or otherwise. However, the general opinion of physicians is that it is what its name implies, and that the derangement of function is but temporary.

Etiology of Dysentery.

The Berlin correspondent of the *Lancet*, November 28, quotes from an account which Staff Surgeon Dr. Jürgens published in the *Deutsche medicinische Wochenschrift*, concerning bacteriological researches carried out by him during an epidemic of dysentery which broke out in a regiment in the exercise camp of Gruppe, in Western Prussia. "The epidemic," says the correspondent, "extended to twenty-six men who presented typical symptoms—namely, severe diarrhœa, hemorrhage from the bowels, and prostration. These twenty-six men were admitted into the military hospitals, and in addition to them were a number of men who suffered from diarrhœa and were treated in the barracks. All the patients recovered in from three to four weeks. The microscopical examination proved that neither entamœba histolytica nor any other protozoon was present in the bowels. Bacteria, of course, were present, and Dr. Jürgens detected a bacillus very similar in form and culture characteristic to Kruse's dysentery bacillus, but showing differences under the agglutination test; probably this bacillus is identical with that discovered by Dr. Flexner in the Philippine Islands. In other epidemics of dysentery, Kruse's bacillus is commonly found in pure culture in the bowels during the first days of the disease, and this bacillus is therefore believed to be the specific germ of dysentery, although the bactericidal action of the serum against the bacillus has not yet been ascertained. In the recent epidemic the bacillus of Dr. Jürgens was agglutinated by the blood. Serum of almost all the patients, both during the attack and during convalescence. The serum taken from patients up to the second day from the beginning of the illness had no agglutinating effect, but on the third day, and afterward, it agglutinated the bacillus of Dr. Jürgens, but not the dysentery bacillus of Kruse. Dr. Jürgens therefore infers that the etiology of dysentery is not in all cases the same, as it is not caused always by Kruse's bacilli, but sometimes by another species. The disease, though a definite entity as to its clinical symptoms, shows marked differences from a bacteriological point of view."

Dr. Davidson, one of the best known British authorities on tropical diseases, expresses his views as to the etiology of dysentery, as follows: "Under the term dysentery, a number of ailments were grouped together, which, as investigation advanced, were coming to be differentiated. Of late years we had been made acquainted with the microorganism of Ogata and Shiga in Japan. Of a similar organism discovered by Flexner in the Philippines; yet a third organism in Egypt. Celli and Fiocca, in Italy, held the bacillus coli dysenteriæ to be the exciting cause, while various pyogenic cocci and certain streptococci had been held responsible for the disease; the bacillus pyolaxeus in America, and the paramœcium in Cochin, China, had each been accredited with being the originators of dysentery. The amœbiæ seemed to be the only constantly found organism in tropical or amœbic abscess of the liver.

Professor Flexner's views with regard to the cause of dysentery are too well known to need recapitulating here, and the same may be said of the conclusions reached by E. B. Vedder and C. W. Duval. Dr. Jürgens' inference that the causal agent of dysentery is not always the same is perhaps warranted by our present knowledge of the disease.

The Effects of Radium on Animal Life.

A Paris correspondent of the *New York Daily Tribune* contributes to its issue of December 27 an article on radium, and especially as regards its effects on animal life. The writer interviewed M. J. Danysz of the Pasteur Institute, who is investigating the pathogenic action of rays and emanations emitted by radium upon various animal tissues and substances. In the course of his remarks M. Danysz said that guinea-pigs were more sensitive to radium emanations than rabbits. Applications of radium rays that create painful sores on the skins of guinea-pigs only act as stimulants or irritants on the skins of rabbits, and singularly enough, cause, in the case of rabbits, a prolific growth of hair. This experiment was made by M. Danysz upon a mouse a month old. A minute glass tube containing one milligram of radium salt was inserted beneath the skin, just over the vertebral column. In three hours symptoms of paresis and ataxia ensued. In seven hours the mouse was seized with violent convulsions of lockjaw, and in twelve hours death occurred. Mice, from three to four months old, subjected to radium rays of the same force, died in a similar manner, and identical symptoms of paresis, ataxia, and lockjaw, and death ensued within a period of from three to four days. From six to ten days were required to kill mice a year old, subjected to the same experiments. Guinea-pigs, upon whom the same experiments were made, resisted the effect of radium for a longer period than did mice of a corresponding age, but eventually they exhibited like symptoms and died. According to the investigator, the result of his studies shows that the nervous centers of animals or insects are extremely sensitive to the effect of the radium rays or emanations. The intestinal organs, on the contrary, are only slightly sensitive to the effect of radium. With regard to the effect of radium on microbes, M. Danysz states that in all cases the further development of the microbe was arrested, but that only in a few cases was the microbe actually killed.

The Changes in Gastric Secretion after Unilateral Nephrectomy.—Stejskal and Axisa found that the hydrochloric acid secretion of the stomach underwent marked diminution even early in nephritis, and were thus led to study further the interrelationship of the renal and gastric secretions. Dogs with œsophageal fistula were used, and their stomach contents studied before and after nephrectomy. Immediately after the operation the secretion began gradually to lose its acidity, until on the third to fourth days no acid whatever could be demonstrated. From this time on the quantity of hydrochloric acid begins to rise again, and about the tenth day reaches the normal. Exact determinations of the other constituents of the gastric juice were not made, but it appeared that the pepsin also was diminished in amount. Owing to the gradual manner in which the change takes place, the authors do not consider the phenomenon as being of reflex nature, and incline to the view that it is due to the changes in the blood produced by the sudden interruption of renal secretion following the operation. The fact that the gastric juice and urine are both acid secretions coming from alkaline blood must be taken into account.—*Centralblatt für innere Medicin.*

News of the Week.

The New Health Commissioner.—Mayor McClellan has appointed Dr. Thomas Darlington Commissioner of Health of New York to succeed Dr. Lederle. Dr. Darlington is a graduate of the Medical Department of Columbia University in the class of 1880.

Typhoid Epidemic in Columbus.—Thirteen cases of typhoid fever have been reported, in the past thirty days at the Ohio Penitentiary in Columbus. It is believed that the infection is due to the water supply, which is from the Scioto River.

Overcrowding in the Cincinnati Hospital.—In the City Hospital of Cincinnati a large number of patients are obliged to sleep on matresses on the floor owing to deficiency of space. In the past two weeks there have been a large number of accident cases in addition to the usual winter increase in medical cases, so that the hospital population is larger than ever before in its history.

Newspaper Contest for Hospital Supplies.—One of the Cincinnati daily papers has offered prizes of supplies to the five charity institutions receiving the largest number of votes from its patrons during the month of December. The prizes will be awarded next week and consist of five hundred dollars' worth of groceries for the first prize, two-hundred and fifty dollars' worth for the second, one hundred and twenty-five, seventy-five, and fifty dollars' worth for the third, fourth, and fifth respectively. A number of hospitals are among the competitors.

Measles Epidemic at Children's Home.—An epidemic of measles has broken out at the Children's Home in Cincinnati. At present there are thirteen cases. The superintendent, Mr. M. V. Crouse, has had to refuse admission to children who have not had the disease.

Intestinal Influenza Prevalent.—There are many cases of intestinal influenza in Cincinnati at the present time, and nearly every office and factory in which many men are employed has a number of absentees. From one line of electric cars alone there are twenty-three men off duty from this cause.

Violent Deaths in Cincinnati.—Coroner Weaver of Hamilton County, Ohio, reports for 1903, 771 violent or suspicious deaths in Hamilton County. Of these, 95 were suicides and 39 homicides. Eighty-nine deaths were due to railway accidents, and 42 to street cars. The remainder were due to miscellaneous accidents and natural deaths in cases in which no physician was called. Of the 95 suicides, 36 took poison, carbolic acid being used in 20 instances. Twenty-four persons ended their lives by shooting, and 11 by drowning. Of the 95 cases 70 were males and 25 females. It is a curious fact that not one colored person is to be found among this number. Among the accidents are 24 deaths from drowning and 5 from tetanus, following slight injuries with blank cartridges.

Insanity among the Indians.—The National Hospital for Insane Indians at Canton, S. D., has just completed the first year of its existence. The superintendent is Mr. O. S. Gifford, and the assistant superintendent and physician Dr. J. F. Turner. The hospital now contains thirty-four patients, and at the present rate of increase in the number of applicants for admission the institution will soon be filled. It is said that insanity is increasing rapidly among the Indians on the reservations, for much of which the enforced civilization of the red man is believed to be responsible.

A Naval Tuberculosis Camp has been established at the Pensacola (Fla.) Navy Yard. The present experimental camp has six patients, and the reports received of the first month's results are most gratifying to the medical authorities. The patients will live out of doors day and night, being sheltered in tents. While it has been decided to establish a naval resort for this class of patients, it may not be located at Pensacola, as Surgeon-General Rixey intends to investigate other localities, one on the Pacific Coast and another in the East, further north. When the experts decide on the best place, Congress will be asked to make an appropriation for the establishment and maintenance of an open-air hospital.

Enormous Legacy to a Hospital.—The will of the late Peter B. Brigham of Boston was sustained by a decision handed down by Justice Lebaron B. Colt, in the United States Circuit Court on December 30, and the $5,000,000 involved will go to the Brigham Hospital. Suit was brought by an heir at law, to have the gift for a hospital declared void, as in violation to the rules against perpetuities. The bill also sought, if that ground were untenable, to have the provisions for the hospital declared invalid as to any excess of property over $1,500,000, for the reason that no charitable corporation, such as was contemplated by the testator, had the capacity under the laws of this commonwealth at the time of the gift to hold property above that amount. Judge Colt decided against the plaintiff on all grounds.

Not a Promoter of Consumption Cures.—United States Consul Smith of Moscow has issued a statement denying that he is coöperating with Kisel Zagoranski (a mining engineer recently licensed by the Russian Government to practise medicine in cases of tuberculosis) in treating consumptives. So far from endorsing the man's methods, he says that the cases brought to his notice have not demonstrated the possibility of curing tuberculosis by the Zagoranski method.

It Has Been Raining in London.—The official meteorological record shows that rain fell more or less continuously in London on 205 days in 1903, or 39 days more than in 1902. The wet did not seem to affect the public health injuriously; on the contrary, it is stated that the death rate in the city and surburban districts was lower than ever before.

The New York Infirmary for Women and Children.—A meeting to celebrate the fiftieth anniversary of the New York Infirmary for Women and Children will be held at the Waldorf-Astoria on Saturday, January 16, at a quarter past eight o'clock. Addresses will be made by Dr William H. Welch of Johns Hopkins University, Miss M. Carey Thomas, President of Bryn Mawr College, Dr. Emily Blackwell, and Dr. Annie S. Daniel.

The Perils of Neglected Vaccination.—How the sin of neglected vaccination finds out its victims is shown by the medical inspector of the Chicago Health Department in his report on four cases of smallpox sent to the Isolation Hospital, quoted in the weekly bulletin of the department: "A man from Oswego, N. Y., visited friends upon his arrival in Chicago while he was in the early stage of smallpox. At the first house he visited there were two young ladies unvaccinated, though they are employed in a large downtown department store. Both are now in the hospital with smallpox, having contracted the disease from their Oswego friend. There was also an unvaccinated man at another house visited by this man, and he, too, is now in the hospital with smallpox. The fourth case, an unvaccinated young man, traveled on the same car with the Oswego man and visited in the same neighborhood."

A Leprosy Scare in Nebraska.—A report obtained currency last week that twenty-five cases of leprosy

had been discovered in the Russian colony near Lincoln, Neb. There was the usual amount of trepidation, but the alarm subsided upon the publication of the report of the Health Commissioner, who made a thorough examination of the suspected men and found them to be suffering from nothing more unpleasant than a common and perfectly benign skin disease.

Beth Israel Hospital.—The annual meeting of the Beth Israel Hospital Association was held and the first anniversary of the opening of the new hospital building at Jefferson and Cherry streets was celebrated in the dispensary of the hospital on December 29. In the last year 82,000 prescriptions have been dispensed, and 1,600 patients have been treated.

Effects of Radium.—At a recent meeting of the Academy of Sciences in Paris, Dr. Roux of the Pasteur Institute presented a paper detailing the results of exposing mice continuously to the action of radium. He hung a tube of radium in a cage containing mice, and after twenty days the animals lost their fur, which subsequently came out again, but was white. Exposure for a still longer period resulted in the production of a general muscular paralysis.

The Pennsylvania State Board of Medical Examiners has just concluded its semi-annual examination of applicants for license to practise medicine in the State. There were 103 applicants examined, and of these only fifty-seven passed. The examinations are said to have been extremely rigid.

Enlarging the List of Notifiable Diseases.—The Philadelphia Department of Public Health and Charities has under consideration the enlargement of the group of diseases notice of which will be required of physicians. As a result of conferences with committees of the Philadelphia County Medical Society and the College of Physicians of Philadelphia, it is proposed to add pneumonia, chickenpox, whooping-cough, tuberculosis, and measles to the list of notifiable diseases.

Dr. Ellen L. Lowell of New York has been appointed chief bacteriologist at the Graves Pathological Laboratory of the Orange Memorial Hospital.

Bequest to Tulane University.—The Supreme Court of Louisiana has decided in favor of Tulane University the first and most important of two contests to the Hutchinson will. By this will about $800,000 was left to the University to be used for its medical department for specified purposes. The first contest was as to the validity of the will, and the second was as to whether the University could act as trustee for one of its departments. The second decision has not yet been rendered, as the brief has not yet been submitted to the Supreme Court.

The Louisiana State Medical Society has changed its meeting place for 1904, as the invitation to Lafayette has been withdrawn. New Orleans promptly put in her invitation, which has been accepted. The unexpected increase in the size and activity of the State Society promised such an unusually large meeting that those in charge of affairs at Lafayette feared that it would be impossible for them to accommodate properly the large crowd expected. The Orleans Parish Medical Society immediately extended a cordial invitation, and is vigorously pushing preparations for the largest and most successful meeting the State Society has ever had.

The Paths of Infection in Tuberculosis.—The third lecture in the course instituted by the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis was delivered in Philadelphia on December 29 by Dr. G. Sims Woodhead of Cambridge, England. Later in the evening a reception was held in honor of the visitor, which was attended, among others, by Mr. Henry Phipps, Dr. George M. Sternberg of Washington and Dr. Wm. H. Welch of Baltimore. In his address Dr. Woodhead dwelt upon the conditions that favor the deposition and the manifestation of the activity of the tubercle-bacillus, pointing out that it may be present on the surface of healthy tissues without doing harm or giving rise to symptoms. In order that it shall manifest its activity special conditions of the host must first be present. Dr. Woodhead showed how the disease develops and spreads, particularly in those portions of the lungs that are little expanded, whether normally from anatomical conditions or pathologically as a result of adhesions or other disease. The various changes in the lungs were illustrated by means of lantern slides projected on a screen. It was pointed out that a catarrhal process of the pulmonary alveoli is the common precedent of invasion. The reaction of the tissues and the resulting histological alterations were briefly considered. Extension takes place through the lymphatics or the blood-stream. The tuberculous nodule may undergo softening and break down, leaving a cavity, or it may undergo fibrosis or cicatrization, and eventually, perhaps, calcification. Involvement of the bronchial lymphatic glands has an important influence on the nutrition of the lungs. In the early stages there may be slight hemorrhage, from the congestion due to the morbid process, while the bleeding in the latter stages results from the erosion of arteries of considerable size. The tendency to the formation of fibrous tissue is the indication of nature's attempt at cure, and is to be encouraged so far as lies within the power of the physician. This process is observed in a large number of cases in which death occurs from other causes, demonstrating the curability of the disease. Not rarely it takes place spontaneously. The physician, however, can contribute largely to the same end by improvement of the general nutrition of the patient and by properly stimulating the functional activities of the respiratory apparatus.

Michael Reese Hospital Receives $1000.—According to the will of the late B. Kuppenheimer, the Michael Reese Hospital of Chicago receives $1000.

Sanitary Investigation by the Illinois State Board of Health.—This Board has just finished a sanitary investigation of seventy-five cities of Illinois, the public water supply of which has been subjected to a careful chemical and bacteriological analysis. The water in the greater proportion of these cities has been pronounced good. The Board has consulted with the local authorities in those cities in which there was evidence of contamination of the water supply, with a view to ascertaining the cause of the pollution, and to suggest a remedy. The sanitary officers of the Board were sent to the majority of the cities for the purpose of investigating insanitary and unhygienic conditions, and to advise the local authorities as to the steps necessary to prevent an outbreak of the disease.

Proposed Medical Legislation in Iowa.—The State Board of Health of Iowa recently held its quarterly meeting, at which a revision of the laws relating to the medical profession was recommended in the following three particulars: First, the creation of a special bacteriological department, which shall have an appropriation of at least $5000 a year; second, the power to act in all cases in which it is believed there is danger of an epidemic or disease, even when there has been no outbreak; third, power to accept the

certificates of physicians from other States that exact the same preliminary training and subsequent examination as Iowa.

Three Hundred Dollars a Day for Medical Services.—Dr. M. P. Morrell of St. Louis has obtained a judgment for $12,666 in his suit for $16,000 for forty days' services rendered the late son of Dr. J. J. Lawrence. Dr. Morrell went to New York to attend Dr. Lawrence's son and rendered a bill for $16,000.

The Newman Club Lectures at Columbia.—The winter course of lectures before the Newman Club of Columbia University was opened on December 15 by Dr. J. J. Morrissey of this city, who chose for his subject, "University Education and Citizenship." A large crowd of undergraduate members was present, and quite a few alumni and invited guests..

Notes on Chicago Hospitals.—The County Board of Commissioners of Cook County is now pushing to completion new cottages for the insane, and for consumptives, at Dunning, Ill.; also a separate building at the Cook County Hospital for the treatment of persons ill with contagious diseases. In addition, plans are being drawn for a central power plant, a ward for working patients, and a morgue and pathological laboratory at Dunning, for a Children's building at the County Hospital, etc. During the year also administrative changes were made at Dunning and at the County Hospital. At Dunning a more thorough system of medical attendance was inaugurated, a partial reclassification of insane patients was made, a pathological laboratory was opened, an interne service installed, and a business manager was added to the official staff. At the hospital an assistant warden, who is a physician and surgeon, was appointed, and changes were made to effect more thorough medical and surgical service for the sick and injured. At the Dunning institutions the average daily number of patients in the insane department during 1903 was 1750, in the poorhouse 950, and in the tuberculosis ward 95.

The total number of patients admitted to the Detention Hospital during 1903 was 1491, of which number 1465 were taken to the various county institutions. At the Cook County Hospital 22,227 patients were treated in 1903; 19,430 were discharged, and 1,996 died. The number remaining in the hospital is 801. The hospital cost the county $312,920 to maintain, or about $1.00 per day for each patient.

Wisconsin College of Physicians and Surgeons.—The faculty of this college will soon erect a $50,000 addition to the present buildings, which will be of red brick, five stories in height, with a frontage of eighty-five feet, and will include a dispensary, a clinical lecture room, a dental infirmary and laboratory, a library and reading-room, and five lecture and recitation rooms.

Obituary Notes.—Dr. HAMILTON A. WEST of Galveston, Tex., died at the home of his brother, Dr. James N. West, in this city, on December 30. He was born at Russell's Cove, Ky., in 1849, and was graduated from the Medical Department of the University of Louisville in 1872. He took up the practice of his profession in Galveston and soon became prominent in medical matters in the city and State. He was for several years secretary of the Texas State Medical Society, and was instrumental in the establishment of the medical department of the University of Texas, in which he was a professor. He was an authority on yellow fever and dengue, and had also made a particular study of typhoid fever.

Dr. JEROME A. ANDERSON of San Francisco died on December 26, at the age of fifty-six years. He was a graduate of the Medical Department of the University of California in the class of 1873. He was an active medical practitioner, but was best known as an exponent of Theosophy, being at the time of his death president of the Federation of Branches of the Theosophical Society on the Pacific Coast.

Dr. JOHN M. OTTO of this city died on December 29 from the result of injuries received in falling from a wooden bridge in front of a house in the course of construction. He was a graduate of the New York University Medical College in the class of 1888.

Dr. ROBERT BOOCOCK, a homœopathic practitioner of Brooklyn, died on December 28. He was born in England, but came to this country in 1870, and was graduated from the Homœopathic Medical College in this city in 1891. He was also a Baptist minister, and at first combined the two professions, but later devoted himself exclusively to medicine.

Dr. FRANCES E. WHITE, formerly of Philadelphia, died December 30, at Jamaica Plain, Mass. She was a graduate of the Woman's Medical College of Pennsylvania in the class of 1872, and for many years was professor of physiology there, but resigned recently on account of impaired health.

Dr. AUGUSTUS D. RUGGLES of this city died on December 27 at the age of sixty-three years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1862.

Dr. BYRON HIRAM DAGGETT of Buffalo died at the Buffalo General Hospital on December 30, death following an operation for the removal of the gall-bladder. Dr. Daggett was a graduate of the Medical Department of the University of Buffalo in the class of 1867. He was a former health physician and police surgeon of Buffalo, a member of many Buffalo medical societies, one of the editorial staff of the Buffalo *Medical and Surgical Journal*, and a member of the staffs of the Emergency, Sisters' and Riverside hospitals of Buffalo.

Dr. ANTON EIDENBENZ, who had practised in this city for over fifty years, died of pneumonia on December 30, at St. Luke's Hospital. He was eighty-six years old. Dr. Eidenbenz was born in Hessedarmstadt, Germany, and was a graduate of the University of Giessen in 1846. He was a surgeon in the Eleventh New York Regiment during the Civil War.

Dr. MICHAEL O'MALLEY died of pneumonia in Philadelphia on December 26, at the age of seventy-eight years. He was a retired army surgeon and a veteran of the Civil War.

Dr. FRANK S. JACKSON died in Dunkirk, N. Y., on January 1, at the age of fifty-two years. He was a graduate of the New York University Medical School in the class of 1881, and subsequently served an interneship in Bellevue Hospital. He practised more than twenty years in Dunkirk. He was a member of the Dunkirk and Fredonia Medical Society, and was a prominent mason.

Dr. T. G. BIRCHETT died at Vicksburg, Miss., January 2, aged sixty-eight years. He was a native of Orange County, Va., and was graduated from the Medical Department of the University of Pennsylvania in the class of 1856. He was twice Mayor of Vicksburg, served several terms in the City Council and the Mississippi Legislature, and was for years superintendent of the Mississippi State Hospital at Vicksburg.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS—ROYAL SPEECH—ARTIFICIAL RESPIRATION—AN INSTITUTE OF THE MEDICAL SCIENCES—BART'S REVERSES DECISION—KING'S—NEW MILITARY HOSPITAL—DR. HARRIS, M. P.—DEATHS OF WM. NEWMAN AND SAMUEL WOODCOCK.

LONDON, December 18, 1903.

THE Prince of Wales presided and moved the report of the Distribution Committee of King Edward's Hospital Fund, at the meeting of the Council on the 15th inst. The treasurer, Lord Rothschild, said the year was not quite ended and he hoped for further substantial donations, but feared they could not show as good a result as last year. The sum to be distributed is about £99,000. The report expresses regret at the retirement of Lord Lister from the chairmanship he had filled so well from the foundation of the fund. It passes on to mention the great expenses required to keep up hospitals to the advances of medical science, and at the same time the tendency of the necessary expenditure on the patients to increase, making the needs of hospitals greater than ever. The Committee view with satisfaction the amalgamation of the National and Royal Orthopædic Hospitals, and are of opinion that one first-rate hospital for this specialty, with its country branch, will tend to the benefit of the patients more than smaller scattered institutions. They even recommend that further sums be set aside to facilitate the possible amalgamation of other charities.

His Royal Highness, in moving the report, expressed hearty concurrence with its recommendations, but had to admit that the hopes entertained last year of an increase of £10,000 to the income had not been fulfilled. The year 1902 was an exceptional one, and some of the reserve at the disposal of the Council would be used to keep up the distribution to that scale. His Royal Highness said this decision was not come to without considering those two opposing principles, one of which deprecates any encroachments on reserves, while the other advocates the expenditure of subscriptions, with a view of relieving present necessities rather than placing them to capital account. "We are anxious," he said, "not to go back in the work initiated by the King, and in the fulfillment of which I consider a sacred trust was confided to me." He then drew attention to the enormous sums for which appeals are now contemplated by the London hospitals—probably over a million sterling will be asked for.

The Lord Mayor presided over the annual meeting of the Sunday Fund on Tuesday. The report showed, as I forecasted for you, the most successful year in the history of this fund. Mr. Coleridge advertised himself by proposing an amendment to the report, and got Archdeacon Wilberforce to second it, about voting money to medical schools, which, of course, the chairman said the fund did not do. A total distribution of nearly £60,000 among the hospitals and allied charities was recommended and agreed to by the meeting.

To the last meeting of the Medico-Chirurgical Society Professor Schäfer sent a paper which was read by the secretary, and described a method of artificial respiration in the human subject, and gave special directions as to the treatment of the apparently drowned. First noticing the Marshall Hall, Sylvester and Howard methods, he passed on to say that, in contradistinction to them, his plan is to keep the subject in the prone position throughout. Laying the patient prone, preferably on the ground, with a thick folded garment under the chest, and the arms laid forward, the operator is to put himself in a position athwart the subject, facing his head and kneeling on one knee, with the other knee and hip flexed, his hands being then placed on each side over the lower part of the back of the chest. He must then slowly throw the weight of his body forward to bear upon his own arms, and so press upon the patient's thorax and force air out of the lungs. This effected, he must slowly relax his pressure by returning gradually to the erect position, but without moving his hands. As this is done, the air is drawn by elastic reaction of the chest wall into the lungs. The process must be repeated regularly at least twelve times a minute, and not more than fifteen. In this way an exchange of nearly 500 c.c. per respiration is effected—more than enough to maintain complete aëration of the blood. The advantages of this procedure are its ease and simplicity, the efficiency of the gaseous exchange as determined by Professor Schäfer, absence of danger from falling back of the tongue (or in drowning cases), obstruction by mucus and froth in the air passages, and absence of liability to injure the liver or other viscera by the manipulations. Directions for treating the apparently drowned by this plan were embodied in the paper.

Dr. Bowles said there were a few points he did not agree with. The method was, in fact, the one he had used for forty-five years—called after Marshall Hall—but omitting the rotation of the patient, which he regarded as often a most necessary part of the plan.

Dr. Silvester said the plan was that of simple pressure and had been in use from early times. The plan proposed in the paper was defective, as it made expiration precede inspiration, and he thought the exchange of air was insufficient. Pressure on the thorax must be dangerous when the heart and other vicera were congested—the parietes might also be injured by vigorous pressure. The plan could not be used in a hot bath.

Mr. Haward thought all the methods known had advantages and disadvantages. He thought, therefore, combining them as Dr. Bowles did was the best practice.

Dr. F. W. Hewitt agreed with this: In asphyxia from anæsthetics the prone position must not be used, and bleeding would relieve the right heart.

Dr. Pembrey also supported the combined plan and venesection. In the still-born the best way was to blow into the lungs. Warmth was important.

Dr. N. Pitt asked if cases of injury to the liver by the Howard method had been recorded.

The President (Mr. Willett) thought the matter had been thoroughly investigated by the committee of the society, and so fully discussed that it would be practicable to draw up new rules for the treatment of the apparently drowned.

This morning the Senate of the University of London issued its appeal for funds to enable it to establish an Institute of the Medical Sciences. As you know from my previous letters, the Faculty of Medicine, consisting of 350 teachers of the University, having ascertained the views of the teachers in our medical schools, recommended the establishment of such an institution for the "teaching of physics, chemistry, biology, anatomy, and physiology." I hear that there is an expectation that land for the building may be granted by the exhibition commissioners, and that would be in proximity with the University, under the control of which the Institute would remain. The step is entirely in accord with the recommendations of the Royal commission and the opinion of the profession—so perhaps the appeal will be successful.

Yesterday afternoon another meeting of the governors of St. Bartholomew's Hospital was held, when it was resolved to take steps to ascertain the possibility of acquiring further additions to the present site. The resolution states that the governors take this course in view of the great encouragement of the press and in other directions, and believing that they have the unanimous support of their medical staff in the action they have decided to take. It is therefore probable that the large scheme pleaded for will be carried out.

By permission of the surgeons, the Schmidt serum for cancer is being tried at the Middlesex Hospital by Dr. Jossé Johnson, whose paper I lately summarized for you. Dr. Marmorek's antituberculous serum is also being tried at the Bompton and St. George's Hospitals. He came over last week and gave some injections, and provided Dr. Arthur Latham with the antituberculous serum to continue the treatment. Perhaps, therefore, we may obtain reliable evidence as to the value of both these remedies.

The donor of the site for King's College Hospital is the Hon. W. F. D. Smith, M. P., who is chairman of the Removal Committee and Treasurer of King's College. He wishes the donation to be associated with the memory of his father, who was for many years treasurer of the hospital. This will, of course, be done, probably by naming the central block after the late leader of the House of Commons.

The new military hospital for London is rapidly approaching completion. It will have 225 beds. The Royal Army Medical College will be built close by. The professors of military surgery and tropical medicine in the college will be at the head of the teaching and clinical departments, and will be assisted by selected officers.

We have another medical M. P. Dr. Rutherfoord Harris, the former secretary of Mr. Rhodes, who was also in the Cape Parliament. As he is a qualified medical man, I hope he will give a good deal of his undoubted talent to medical topics.

Dr. William Newman, Consulting Surgeon of Stamford Infirmary, died on the 3d inst., in his seventy-first year. He was one of our greatest provincial leaders, eminently scientific, with rare clinical insight and operative skill. One who preserved his integrity throughout, and was trusted to the utmost by his brethren.

Manchester mourns "Sam Woodcock," who died suddenly on the 12th inst., aged sixty-three years. You may remember his name best as the zealous medical reformer. Manchester knew him as a citizen devoted to well-doing, taking an active interest in her public affairs, and advocat-

ing with great eloquence everything likely to promote the good of his fellow citizens. A man of strong opinions, pushed logically but never offensively, of sterling character, Dr. S. Woodcock could not confine his work to his profession, but he did not neglect this as many a grateful patient will testify. He would have been sent to Parliament but for private reasons preventing his coming forward.

Progress of Medical Science.

Journal of the American Medical Association, Jan. 2, 1904.

The X-ray as a Therapeutic Agent.—A. D. Bevan considers this question with special reference to cancer. He considers the ray indicated, in the light of our present knowledge: (1) In superficial epitheliomas; (2) as a post-operative treatment in most of our carcinoma cases; (3) in inoperable cases, as a justifiable piece of experimental work in the hope that this line of investigation may possibly lead to valuable results. The dangers of the *x*-ray as a therapeutic agent are two, and these dangers should be especially pointed out to the general profession. The first danger is the possibility in all cases of producing a serious *x*-ray burn. This possibility can be reduced to a minimum by a thorough understanding of the technique, but cannot be entirely done away with, as burns will occur even in the hands of experts of the greatest experience. The second danger, and the more important one, is the using of the *x*-ray in cases in which it should not be used, in which its use is of no benefit to the patient, means valuable time lost, and prevents the patient receiving the greater chances of cure offered by radical surgical removal of the disease.

Perisinusal Abscess of the Lateral Sinus.—A case of this nature with metastases in the liver and sternoclavicular joint is described by Gordon King, whose patient was a white boy aged fourteen years. Operation consisted in exposure of the mastoid, opening the antrum and laying bare the lateral sinus in the posterior aspect of the mastoid opening, whereupon pus began to ooze from between the sinus wall and the upper part of the wound. This was traced up and found to come from a cavity containing about a drachm of creamy yellow pus in contact with the membranous wall of the sinus. This was freely exposed, evacuated of pus and a gauze drain applied. The sinus seemed to be normal otherwise and exploration brought out a flow of pure liquid blood. There was no evidence of thrombophlebitis. Three hours after operation the patient had a chill and evidences of inflammation in the left sternoclavicular joint. These subsided, but returned later, so that an incision was made into the joint, but no pus was ifound. The patient had had considerable pain over the liver and spleen previous to operation, and had evacuated pus and blood from the bowels. Three days after operation these abdominal pains returned and he vomited a little blood. This happened again five days later, but from this time convalescence was rapid and uninterrupted and in three weeks the patient was well.

Diabetes Mellitus: the Limitations of Its Dietetic Treatment.—This topic is discussed by A. R. Elliott, who declares that the course to be followed in the dietetic treatment of diabetes is, in the amenable stages of the disease, to allow the patient as liberal an allowance of carbohydrates as the patient can assimilate, and in the severe stages as much as is found necessary to hold in check the dystrophic advance, bearing in mind the important fact that carbohydrates only act as albumin-sparing bodies when their ingestion is followed by at least partial assimilation. At the same time every artifice must be employed to introduce the largest amount of fat that the patient can take. If this method is pursued it does not become necessary to restrict the nitrogenous elements of food, for by the judicious introduction of carbohydrates and fats little necessity exists for excessive devotion to any one class of foods, and seldom is the patient led into over-indulgence in animal foods. The point is frequently made that it is as necessary to limit the quantity as it is the quality of the foods in diabetes. It seems to the writer an unnecessary cruelty to limit the amount of available foods to these patients, for the bulimia is the outcry of starved tissues, deprived of the food values necessary for their preservation, and to meet this tissue hunger by further starvation seems both cruel and unscientific. A better solution of the difficulty is reached by adjusting the diet, as far as possible, so as to provide sufficient food calories for the systemic needs in easily available forms, such as carbohydrates, fats and alcohol, and when this is successfully accomplished the excessive craving for food disappears.

Medical News, January 2, 1904.

Chickenpox Concurrent with Smallpox.—Philip D. Bourland emphasizes the following points: In his observations, the concurrence of smallpox in no way caused the course of the cases to depart from that typical of chickenpox. Vaccinated and unvaccinated children showed equal susceptibility to infection, and the course of the sickness was the same in each class. This fact excludes varioloid. None of the writer's patients had ever been exposed to smallpox or had ever had it. No adults were attacked notwithstanding the absence of vaccination in a majority. Five of the children exposed had had chickenpox in a previous epidemic, these previous attacks conferring immunity except in one instance. Smallpox and chickenpox are distinct pathological entities, and though in intimate association, neither disease influences in any way the natural history of the other.

Thoughts on Chlorine and an Antiseptic Technique.—Douglas H. Stewart states that after testing many soaps the ordinary brown laundry variety always seemed sterile, but he has never seen sterility of the hands from the use of any soap. If soap is eliminated from the technique, the following method is suggested: Mix a heaping teaspoonful of calc. chlorat., of table salt and of aq. ammoniæ in a quart of cold water; bleach and cleanse the hands therein, and they will often be sterile. Special attention should be paid to the nails—powdered pumice stick and brush being used. Chlorinated lime under and around the margins of the nails is very cleansing. In the case of pregnant women, the advice is given to daily wash the mons veneris and all about the private parts with water, two quarts, a heaping teaspoonful of calx of salt and a half teaspoonful of pot. carb. This is allowed to dry on the skin. The following method of sterilizing the hands is given: Five minutes mechanical—pumice, brush, hot water, green soap, and wooden nail-cleaners. Five minutes chemical—two heaping teaspoonfuls of fresh calx chlorat. and one teaspoonful of U. S. P. acetic acid to the pint of sterile water. It should be remembered that all chlorine solutions depreciate very rapidly.

The Management of Typhoid-fever Epidemics.—George A. Soper believes that after an epidemic has declared itself, nothing can do more good than to take prompt steps to determine the presence and nature of the disease. Reliance should never be placed upon clinical symptoms alone in the diagnosis of typhoid fever. When utilized to the fullest extent, the Widal test can be of the utmost value at the outbreak of an epidemic of a disease which is suspected to be typhoid fever. The number of cases of sickness should be accurately determined; also where they are distributed and when they occurred. The collection and intelligent analysis of the vital statistics are an indispensable feature in the control of an epidemic. Special care should be taken to detect the existence of mild, unusual, and atypical cases. An epidemic is not so likely to spread from the severe cases as from the mild ones. As soon as possible, the original cause of the epidemic should be looked for and removed. Local health boards may control the purity of food supplies by regulations covering the quality of these products offered for sale. Disinfection on a large scale will generally be required in a typhoid-fever epidemic. In cases in which the bladder is infected, urotropin given in 10 gr. doses three times a day for a week, has been found to be effective. The State should send a representative to remain long enough at the seat of epidemic to insure the adoption of measures which will bring it under control, however long this may take.

New York Medical Journal, January 2, 1904.

The Ocular Complications of Mumps.—J. H. Woodward has searched the literature of this subject and finds records of abscess of the lids, bilateral conjunctivitis, keratits, iritis, inflammation of the lachrymal glands, paralysis of accommodation, double amblyopia, and optic neuritis, He adds the history of a personal case of optic neuritis which has been under observation for eighteen months, his patient being a girl of twelve years. The patient came through several constitutional diseases following mumps with one eye normal while the other was somewhat impaired.

The Treatment of the Cardiac Toxæmia of Pneumonia.—H. L. Elsner says that the clinician should constantly keep before his mental vision in treating pneumonias, the association of a feeble heart with dilated peripheral vessels and altered blood-pressure. The prime factor in the disease is a toxæmia with obstruction in the pulmonary circuit. This leads to cardiac asthenia, especially in the right heart with degenerative changes in the heart muscle, heart-clots, and vasomotor paralysis. The toxæmia is short lived, but the condition is dangerous. All depressants must be avoided. Nitroglycerin must not be used indiscriminately. Venesection is often preferable. Veratrum viride is contraindicated. The preferable remedies are the cardiac stimulants, such as digitalis, strychnine, and adrenalin. The latter acts on the heart and vessels,

but not on the vasomotor centers, and thus may be used to assist strychnine. To combat the cardiac asthenia he prefers to give every fifteen minutes fifteen drops each of the compound spirit of ether, aromatic spirit of ammonia, the compound spirit of lavender, and the tincture of valerian. This is kept up day and night until the pulse shows improved tone and the heart action is decidedly better. If alcohol is needed, he prefers it in the form of Tokay wine. Occasionally one may need high rectal injections of coffee and whiskey and hydopermic injections of ether, sterilized oil and camphor. Saline solutions, subcutaneous or intravenous, are called for in desperate straits.

Surgical Treatment of Gallstones.—B. F. Curtis discusses the pathology and complications of gallstones and gives the histories of five cases. His conclusions are as follows, as to the advisability of early operative intervention while the stones are still in the gall-bladder or cystic duct and before the onset of infection: (1) The serious accidents of infection are avoided and any inflammatory condition which may exist can be improved or cured, just as drainage cures urinary cystitis. (2) The stone is removed before it enters the common duct, thereby preventing all the dangerous consequences likely to follow the presence of a stone in that passage. (3) Further attacks of cystitis and colic are prevented. (4) Further calculus formation is prevented or impeded. for the stones are formed in infected gall-bladders, and the latter may be removed by operation or rendered so healthy by drainage that no more calculi will form. (5) It must be remembered, also, that latent cases are by no means free from danger, so that the individual who has recovered from an attack of colic cannot be considered cured, even if he is entirely free from symptoms for years, as it is probable that stones remain behind, or that some chronic cholecystitis persists. The possibility of secondary pancreatitis must be kept in mind, and also that of cancer of the gall-bladder, which is more common than has been supposed. (6) Without reference to more important results, it is the general feeling of those with experience in the surgery of cholelithiasis that in the latent cases, while the patients do not present symptoms pointing directly to the biliary system, they are afflicted with various dyspeptic complaints, and that the latter can be relieved or permanently cured by operation.

American Medicine, January 2, 1904.

Seasickness: Etiology and Prophylaxis.—E. Kirkland Shelmerdine attributes seasickness to three factors, acting together or independently—mechanical, mental, and the irritating influence of the bile in the stomach. In walking on shipboard, the individual undergoes many muscular contractions. The muscles of the trunk and legs undergo excessive activity, and the diaphragm is elevated by the muscles of the chest during inspiration. Many go on board ship in a bilious condition. From muscular contractions and pressure, the bile is forced into the intestines. The elevation of the diaphragm causes a negative pressure in the stomach, and the abdominal pressure aided by constipation causes the bile to flow into the stomach. The bile is a foreign body in the stomach and excites vomiting. Prophylaxis should begin ten days before sailing: Podophyllin, 3 mg. ($\frac{1}{20}$ gr.) four times daily. On the third, sixth, and the day before sailing, calomel is given—.13 gm. (2 grs.) in divided doses. The night before sailing, a bottle of magnesium citrate should be given. Five days before sailing, sodium bromide, .32 gm. (5 grs.) twice daily, is given, and this is continued till "sealegs" are acquired. The bowels must be kept loose on shipboard. The main object is to cleanse the bowels and to get rid of as much bile as possible. In cases of persistent vomiting, washing out the stomach and bowel is beneficial. Strapping the chest will quiet the stomach. The body should be relaxed and not held stiff. It should follow as far as possible the movements of the ship. There is also a nervous element in seasickness which causes lack of confidence in one's ability to navigate.

The Early Diagnosis of Arteriosclerosis.—Alfred Stengel states that in the processes of involution that occur with advancing years, the primary, most widespread, and important, is the loss of elasticity of the blood-vessels and their hardening. No researches have as yet thrown any definite light on the particular causes of physiologic senility. However, considerable light has been thrown on the factors concerned in the premature development of this condition. Early recognition of the development of this condition and a proper regulation of the life and habits of the patient may postpone the more advanced stages of the affection, if indeed they cannot cause a restitution of previous conditions. Arteriosclerosis may be localized or diffuse. It is important in the diagnosis of this trouble to consider the involvement of the smaller vessels first. Among the more definite and direct causes of arteriosclerosis are, laborious work, overuse of alcohol overfeeding, chronic metallic poisoning, and some infectious diseases, particularly syphilis. Heredity must be remembered. The first effect of loss of elasticity of the blood-vessels is an impediment to the easy circulation of the blood. The heart's work is increased, and the blood-pressure is increased. In the first heart-sound there is an early lenghthening and an increased heaviness, from augmented muscular action. At last a murmur develops. The second heart-sound is accented early. There is a tendency to increase of the tidal wave as shown by the sphygmogram. Among the early clinical symptoms are a change of vigor and of color, and various trivial evidences of reduced vitality. The writer believes that neurasthenia is cardiovascular in origin far oftener than is believed. The activity of the sweat glands is sometimes pronounced. The urine in many cases shows various changes from the normal. Increase of the total amount seems to antedate any acute actual disease. Various early symptoms testify to the affection of the heart when it is especially affected. The writer finally calls attention to the possibility of an early diagnosis by ophthalmoscopic examination. The high light of the arterial image gives evidence of thickening of the retinal arteries.

British Medical Journal, December 26, 1903.

The Stage of Invasion in Measles.—R. W. Marsden states that according to v. Jürgensen, prodromata may be practically absent in an attack of measles, or constitutional symptoms may arise soon after infection occurs. More common are instances in which the prodromal stage of invasion is unusually prolonged. The writer then cites two cases in which the exanthem appeared on the sixth day from the onset of pyrexia. The stage of invasion in measles may be of very variable duration.

Acute Rheumatism: Five Cases of Apparently Direct Infection.—E. Sydney Hawthorne reports these cases, all in one family. The first patient was the eldest son, thirty years old. Acute rheumatism was diagnosed. A few days later the second son was attacked with the same symptoms. Next the eldest daughter complained of pain, and swelling in the joints, feverishness, loss of appetite, and sleeplessness. The second son died. The father and youngest son were then attacked by the same disease. The case of a daughter who, though not living at home, was a constant visitor at the house is next reported. She had an attack which was considered to be one of acute rheumatism. All of these cases, with one exception, have been examined by two independent medical men, and some by three. The writer believes the cause of these cases of acute rheumatism to be direct conveyance of the disease from one patient to the other.

On the Relation of the Argyll-Robertson Phenomenon to Syphilis.—J. Michell Clarke, after analyzing a series of cases, draws the following conclusions: A previous syphilitic affection is not sufficient without some further change to lead to the presence of the Argyll-Robinson phenomenon, and in thirty-seven cases of cerebral and spinal syphilis, in which the mischief was confined to the ordinary visceral lesions of that disease, that is gummata, gummatous meningitis, syphilitic endarteritis, the sign was not typically present. In similar cases in which it may be present, and in other cases with a history of past syphilis in which it occurs as an isolated sign of disease, it is evidence of a further degenerative process at work within the nervous system. This degenerative process is to be regarded in the large majority of cases as a parasyphilitic one, although in a certain proportion, proof of this is wanting, and there is possibly some other cause at present obscure. This degeneration may remain stationary at an early stage without further development for long periods. If these observations are correct, the Argyll-Robertson phenomenon is an even more important sign of disease than it has been previously considered.

Some Observations on the Temperature of Coma.—James E. H. Sawyer writes that in certain conditions associated with coma the bodily temperature is well known to deviate considerably from the normal, as is the case in the high temperature of pontine lesions, and in the low temperature of diabetic coma. The writer has never met with a case of diabetic coma in which the temperature was higher than 99° F. There is considerable difficulty in explaining the cause of this subnormal temperature. In uræmic coma the temperature is most commonly normal. But often a few hours before death there is a rise in temperature. In intracerebral hemorrhage the temperature rises above normal within twelve hours, as a rule, and the earlier this rise commences the more serious is the prognosis. In comatose patients suffering from fracture of the skull, or from concussion, the temperature in three cases was recorded as 95°. In patients in a comatose condition from alcoholic poisoning, the temperature is nearly always considerably below normal.

In some cases in which the cause of the coma is not evident, the temperature will sometimes clearly indicate its nature, as between uræmic coma and that due to cerebral hemorrhage. If the temperature is above normal soon after the onset of the coma, the prognosis is nearly always unfavorable.

Deutsche medicinische Wochenschrift, December 17, 1903.

Marmorek's Tuberculosis Serum.—Goldschmidt has waited until Marmorek himself made public the results of his work before announcing his experiences with the same serum, which he employed in a number of cases during the evolution of the product. In no instance was any improvement noted, and he advises the greatest caution in administering the serum to patients, especially advanced cases and pulmonary cases with much temperature. He considers Marmorek's preparation as little else than a somewhat modified tuberculin, and proposes the following plan of his own. A cow affected with perl sucht, which is the form of animal tuberculosis most nearly approaching the human pulmonary lesion, is injected with tuberculin until an intense reaction is produced. At this moment, when the blood must be full of antitoxin, serum is to be taken from the animal and injected into another healthy cow. By repeated treatment in this way it may be possible to obtain an antitoxin which will be more in accord with Marmorek's own theory. The questions of whether antitoxin is formed at all in such a way as this, whether the tubercle bacillus does its destructive work through a toxin, and if so, whether it is to be neutralised by an antitoxin, are, however, still *sub rudice*.

Contributions to the Morphine-Scopolamine Narcosis.—Volkmann joins himself to the ranks of those who advocate this method of anæsthesia. Twenty cases, mostly women, were subjected to laparotomies and other equally serious operations under this plan without any undesirable by-effects being manifested. The method employed differs somewhat from that of other authors and consists in giving hypodermatically 12 dmg. of scopolamine hydrobromate and 1.5 cg. of morphine four hours before the operation. Two hours later the same dose is repeated, and fifteen minutes before the operation 3 dmg. of scopolamine and 0.5 cg. of morphine are injected. Shortly after the first dose the patients fall into a tranquil sleep, which gradually deepens to complete insensibility and lasts for from three to eight hours after the last injection. A small amount of ether by the drop method was given in a few cases during parts of the operation. The pulse was usually moderately accelerated, the pupils were dilated or contracted, and reacted sluggishly or not at all to light. The other reflexes were present, but diminished. Post-operative nausea was observed in four cases. The author regards the method as safe and by far the most agreeable for the patient yet in use.

The Glycolytic Ferment.—Blumenthal has found that by expressing the juice of the tissue cells in a hydraulic press he was able to obtain a fluid having the property of breaking up sugar, and that it is this that is mainly active in the normal glycolysis. This ferment, which may be universally present throughout the tissues, destroys sugar under the formation of carbon dioxide, fatty acids, and small amounts of alcohol. The pancreas is the source of another agent which has the property of increasing the glycolytic activity of this ferment throughout the body, but the *modus operandi* of this process is still uncertain. Although blood serum appears to contain some anti-glycolytic body which prevents the decomposition of sugar in the blood itself, the leucocytes appear to act as carriers of the glycolytic ferment and deposit it in the muscles, where it may, perhaps, be rendered active by the substance secreted by the pancreas. In advanced cases of diabetes the liver has been found devoid of glycolytic action, though the power of glycolysis is not altogether abolished in dogs from which the pancreas has been extirpated. The author is now engaged in attempting to obtain the glycolytic ferment of the tissues in a form that will make possible its subcutaneous injection as a therapeutic measure in diabetes.

The Destruction of Pathogenic Organisms in Milk by Heat.—Tjaden points out the difficulties of this problem, which requires a method that shall be effective, practicable for large establishments where enormous quantities of milk have to be handled in a short time and shall not interfere with the taste and digestibility of the milk or its adaptability to the manufacture of the usual dairy products. The most important factor is undoubtedly proper attention to cleanliness at the source of supply; but as this will be achieved only after the producers have learned that the extra care taken in the barnyard means a greater market value for the milk, other measures must also be developed. Heating milk for from one to two minutes to a temperature of 85° C. is sufficient to kill the germs of the ordinary infections, but occasions certain changes in the milk. These are so slight as to be negligible for all purposes except the manufacture of hard cheeses. Heating to 60–65° C. for a period of one hour also seems to assure safety, though this is not yet altogether certain, and the milk does not suffer by the process. Further investigation is necessary to determine what procedure intermediate between these two will be most practicable for routine use in large dairy establishments.

Berliner klinische Wochenschrift, December 14, 1903.

Animal Inoculation and Renal Tuberculosis.—Salus believes that the difficulty often experienced in finding the organism microscopically in urinary sediments, and the many fallacies likely to be encountered in endeavoring to identify it either by staining or by culture make the direct detection of the tubercle bacillus in urine a very uncertain proposition. While the smegma bacillus does not occur as a contamination in the urine of men nearly so often as in that of women, all specimens to be examined for the tubercle bacillus should be obtained by catheter and received into sterile receptacles, after a preliminary sterilization of the meatus and flushing of the urethra; the first portion is to be rejected. Inoculation of guinea-pigs is still the most reliable test for the existence of the tubercle bacillus in the urine, for in the very rare instances in which extraneous infection of the laboratory animals occurs, the lesions are always distributed in such a way as to leave no doubt as to the nature of the infection. Inoculation in the groin is much preferable to the usual practice of intraperitoneal injection, as fewer animals perish through mixed infections, and the local lesion can be more satisfactorily studied by excising an enlarged gland, if an early diagnosis is necessary. Negative results are of more value than positive, for it has been shown that the kidneys of tuberculous patients frequently undergo changes making them permeable to the tubercle bacilli, and in other ways simulating renal tuberculosis.

Cyclic Albuminuria.—Hauser says that two types of this condition must be recognized. In some cases casts are at times to be seen, even though but rarely, and in very small number, while in others, no matter how carefully one searches, formed elements are never found. The former are undoubtedly to be ranked with the true nephritises, but there is still considerable difference of opinion in regard to the status of the latter, which are the true orthotic cases. In fourteen cases which the author has studied and kept under observation for years there has been a distinct connection between the origin of the disease and some infectious disease which frequently was attended by a more or less severe grade of nephritis. The author's view is that the disease is essentially functional and depends on disturbances of circulation, and perhaps partly on the toxic effect of the products of muscular activity acting on a renal epithelium damaged by a former infectious process. The seat of the lesion must be assumed to be the epithelium of the tufts of the glomeruli. He considers that the standpoint of those who advise no treatment of the condition, under the belief that the trouble will be outgrown, is mistaken and likely to permit future exacerbations of serious nature. He has found the most effective system of treatment one which begins with diet and rest in bed, which are continued until the albumin has disappeared for a considerable length of time. A regular system of training the kidneys to resist the products of muscular work is then begun by allowing only the most gradual return to normal activity, each reappearance of the albumin being an indication that the pace has been too rapid, and that a return to a more restricted *régime* is necessary. A number of the author's cases have been permanently cured in this way.

Münchener medicinische Wochenschrift, December 1, 1903.

The Action of the Röntgen Rays on Animals.—Heineke found that mice were particularly susceptible to the effects of exposure to the Röntgen rays, dying usually in from six to ten days after exposures aggregating from five to nineteen hours; guinea-pigs were less easily affected, though exposures aggregating fifteen to thirty hours were fatal in seven to fourteen days; the younger animals were killed promptly while some large and vigorous individuals did not die at all. The autopsies showed marked pigment formation in the spleen and slight degenerative changes in the central nervous system. The other organs were normal, and the author ascribes the deaths to some destructive action of the rays on the red blood cells.

The Ultramicroscopical Examination of Solutions of Carbohydrates and Albumins.—Raehlmann, by the use of the new microscope of Siedentopf and Zeigmondy, has discovered facts having an important bearing on the behavior of substances in solution. The instrument depends on the principle of intense focal side illumination and is

capable of rendering visible particles only one-tenth $\mu\mu$ in diameter. A study of solutions of various coloring matters showed that they were really composed of minute particles which appeared to be characteristic in form and motion for each substance. In albuminous solutions the particles are so densely crowded together that only in a dilution of one-one hundred thousandth is it possible to distinguish them separately. From observations on albuminous urines the author believes that the method can be used to advantage both in the quantitative and qualitative determination of albumin. Various carbohydrates, such as dextrin, lactose, and dextrose, exhibited similar appearances, while glycogen particles can be recognized in a dilution of one-three millionth and have a diameter of about sixty $\mu\mu$.

Functional Kidney Diagnosis without Catheterization of the Ureters.—Voelcker and Joseph have found that indigocarmine is excreted by the kidneys with sufficient regularity and promptness to make it a reliable indicator of the functional efficiency of the two organs. The difficulties of ureteral catheterization and of the necessary freezing point determinations of the blood and urine have made the newer functional diagnosis of renal lesions more theoretical than practical and the author's method accomplishes the same purposes in a much simpler manner. Indigocarmine, which is the substance used by Heidenhain in his epoch-making studies of kidney function, has many advantages over the other pigment, methylene blue, which has previously been employed in renal work. It is non-toxic, is excreted only by the kidney, does not suffer any change in its passage through the body, and its appearance in the urine begins within a very short time after its administration, reaches a maximum in thirty minutes and comes to an end within ten hours. The authors inject into the gluteal muscles four cubic centimeters of a warm sterile 4 per cent. solution of indigocarmine in physiological salt solution. On introducing the cystoscope the urine is seen to leave the ureteral openings in jets of blue-colored fluid which gradually disperse like puffs of smoke. Not only is the finding of the ureteral orifices greatly facilitated, but it is possible to determine positively the existence or non-existence of two secreting kidneys and to estimate the relative proportion of the work done by each as indicated by the comparative size, frequency and force of the two streams. The method has been used successfully in a number of cases in which the results have been controlled by operation or autopsy and its value demonstrated.

Münchener medicinische Wochenschrift, Dec. 15, 1903.

The Formation of Antibodies after the Injection of Zymose.—Jacobsohn injected sterile yeast into goats and rabbits for the purpose of producing bodies active against the fermentation of sugar. Several specimens of sera were obtained, and their action in inhibiting fermentation in sugar solutions tested. It was found that the characters of the products of the different animals differed greatly, but one serum was distinctively active and was capable of neutralizing three to four times the amount of yeast injected into the animal. It was found that the normal serum used as a control had a slight inhibiting power on zymose fermentation.

Combined Alkali and the Titration of Gastric Juice.—Volhard, in working on his method of pepsin determination, found that his results with phenolphthalein were all too high. Further investigation showed that the presence of peptone, titration with one-tenth N. NaOH, using phenolphthalein as indicator must, in order to obtain the end reaction, always be carried beyond the point at which the reaction to litmus is strongly alkaline. The fact that albuminous bodies combine with bases as well as acids has not heretofore been considered, and the combined *alkali* of gastric contents must be taken into account just as much as the combined acid. Naturally the combined alkali is greater on albuminous diet, and different results are obtained with test-meals and test-breakfasts. Töpfer's method is based upon a wrong assumption, yet yields results approximately correct. He titrates the free HCl with dimethylamidoazobenzol, and then assuming that olizarin reacts to all acid factors except the combined acid, in order to obtain the amount of this subtracts the olizarin titration from that with phenolphthalein. As a matter of fact, with the olizarin he has already titrated the free and most of the combined acid, and what his subtraction really gives is the combined *alkali*. The values of the combined acid and alkali are nearly the same, however, so that the result is not far from right. The values hitherto obtained for the total acidity are too high, owing to this peculiarity of phenolphthalein which belongs to Glaser's group iii of indicators which are very sensitive to acids and but slightly sensitive to alkalies. To obtain the true total acidity, the titration should be carried out with olizarin or litmus as indicator.

Post-traumatic Nephritis.—Oberndorfer describes a case in which a trauma, insignificant in itself, produced a serious lesion leading to the individual's death. The patient, a man of forty-nine years, slipped in descending a stairway so that he skipped the last step and landed heavily on the right foot, but did not fall. He immediately experienced severe pain in the heel and was at once put to bed. No lesion was to be detected about the foot, and gradually the pain and loss of function improved so that in two weeks he was able to leave the house. From the time of the accident, however, the pulse was very rapid and there was much general disturbance showing itself in extreme unrest and insomnia. The patient returned from his first walk out of doors greatly fatigued, and several days later had a severe nasal hemorrhage, speedily followed by hæmaturia and pain in the region of the left kidney. Sugar and albumin were present, the hemorrhages from the kidneys continued, and the general weakness persisted until death followed, on the twenty-third day after the injury. The autopsy showed that the organs, excepting the kidneys, were fairly normal. There were hemorrhagic extravasations into the abdominal muscles and the pelvic muscles, particularly the psoas and quadratus lumborum were completely infiltrated with blood and necrotic. There was a hemorrhagic collection about the upper pole of the left kidney, and both kidneys were the seat of extreme fatty degeneration. The author ascribes the condition to the sudden compression of the organs through the forcible contraction of the various trunk muscles in the act of keeping the balance when about to fall, whereby the twelfth ribs also were driven against them, and the starting-point of the hemorrhages produced. It was discovered that the patient had a past history suggestive of hæmophilia, and this no doubt contributed to the progress of the lesion.

Archives Latines de Médecine et de Biologie, October, 1903.

The Filaria Found in Dog's Blood.—Gustavo Pittaluga reports the result of his studies in regard to this parasite (F. immitis), which finds a temporary host in the Anopheles mosquito. By the use of methylene blue as a staining agent, the whole cellular structure of the embryo is clearly shown and is described in detail by the author.

Gout in Spain.—Francisco Huertas finds that in 1900 the mortality from gout in Spain was 348, which is not a very satisfactory showing. In some of the northern provinces when the peasants have made changes in their diet, especially in regard to maize, the disease appears to be diminishing. Still, the connection between maize and gout has not been absolutely proved, and the author observes that if the disease be due to microorganisms, to hyphomycetes, yet it has not been demonstrated that these are exclusively parasites of maize.

A New Method for the Demonstration of the Intrinsic Fibrilæ of Nerve Protoplasm.—Ramon y Cajal submerges small fragments of nerve tissue in a solution of silver nitrate, then in pyrogallic acid, formol and distilled water, washing them finally in water and alcohol. The various layers of the preparation are differently stained, but the neurofibrillæ of the intermediate layers are distinctly visible in black, or chocolate or coffee color on a yellowish ground of protoplasm and nucleus. They show that, contrary to the opinion of Bethe and of Meyer, the pericellular nerve branches do not terminate in Golgi's plexus, but of themselves constitute a plexus or *terminal nest* with free extremities. Large primary, and finer paler secondary filaments are clearly shown by this new method.

The Cytological Study of the Inflammatory Liquid Products from Serous Membranes, Especially the Cephalorachidian.—A. Signorelli concludes that in all inflammation of serous membranes there is a general and a local cellular reaction. Polynucleosis is the characteristic of a general reaction of the tissues and organism and is found in all acute processes. Lymphocytosis indicates a local reaction of the organs and lymphoid tissues of serous membranes and deep layers, and is found in subacute and chronic processes. The author does not admit any essential difference between exudates and transudates, both depending upon a more or less severe or more or less prolonged inflammatory process of the serous membranes.

A New Method for the Differentiation of the Colon Bacillus and the Typhoid Bacillus in Malt Broth.—Eduardo Xalabarder and Felipe Proubasta prepare a malt broth, in which they sow the two kinds of bacilli in separate tubes. Within a few hours there is germination of both, then precipitation and transparency in the Eberth tube, slight precipitation and opacity in the coli; encapsulation of both germs, swelling and deformation by partial destruction of the typhoid bacillus, strangulation and bipartition of the other. These same morphological changes occur under the microscope when the two kinds of bacilli have been cultivated in the same tube. The authors believe that these modifications are probably due to some substances of recent formation in

the culture broth by the biochemical action of the microorganisms.

The American Journal of the Medical Sciences, October, 1903.

Multiple Myeloma (Myelomatosis), with Bence-Jones Proteid in the Urine.—F. Parkes Weber, R. Hutchison and J. J. R. Macleod conclude: (1) That Bence-Jones albumosuria is always the result of disease of the bone-marrow. (2) That it is due to an abnormal metabolic or degenerative process in the myelocytes or in tumor cells derived from the myelocytes or their predecessors. (3) That the reason why it is generally, though not always, associated with myelogenic tumor formation is that the tumor cells derived from bone-marrow cells, however much they may morphologically resemble true bone-marrow cells, are more prone to abnormality (including unusual degenerative changes) than real myelocytes are. (4) That non-myelogenic tumor cells are not affected in the same way, and therefore metastatic tumors in the bone-marrow do not give rise to Bence-Jones albumosuria.

The Occurrence of the Bence-Jones Albumin in a Pleuritic Effusion.—Isador H. Coriat reports a case in which the Bence-Jones albumin could be demonstrated in large quantities in the pleuritic effusion of a patient suffering from multiple neuritis associated with extreme tenderness of the ribs, while it was absent from the urine. The substance was preëminently of an albumose nature, although probably not a true albumose, and having all the characteristics of the Bence-Jones albumin, but existing in the pleuritic fluid in an unusual physical state. It evidently was not absorbed and did not pass into the blood stream, as not even a trace of the substance could be detected in the urine. It seems to be a derivative of the digestive action of either the leucocytes of the bacteria upon the proteids in the effusion which are derived directly from the blood. Its origin can probably be traced to serum globulin rather than to serum albumin.

Rare Case of Appendicular Abscess Situated between the Layers of the Mesentery of the Small Intestine.—Joseph C. Bloodgood reports this case as the first instance of a definite localized abscess which he has observed to be situated between the folds of the mesentery of the small intestine, nor previous to this observation had he ever been able definitely to demonstrate that an appendicular abscess was due to the perforation of a round intestinal worm. The patient was a child of eight years, and for a number of months had had attacks of abdominal colic at irregular intervals, and had on a few occasions passed a round worm. The writer saw the patient thirty-six hours after the beginning of the illness. The middle-line incision was used, as it was the only way properly to drain the abscess and protect the peritoneal cavity. Twenty-seven hours after drainage of the abscess, a second operation for obstruction was performed. From the clinical picture, definite obstruction was not certain, but in view of the extensive gauze drainage, the writer did not consider it wise to delay for more definite symptoms. In the abscess cavity were two or three round worms. Several worms perforated the wall of the intestine about the drainage tube. The fecal fistula which was formed demanded the most careful attention. When the obstruction was relieved, the fecal fistula was closed. A long lateral anastomosis was made. Four weeks after operation the wound was completely covered with epidermis. Nine months after the operation the patient was in perfect health.

Tortuosity of the Aorta.—Joseph Sailer and G. E. Pfahler have made a series of studies upon lesions of the aorta, including clinical examinations combined with fluoroscopic and radiographic examinations. It is not easy to give a clear picture of the symptomatology of the condition of atheroma of the aorta leading to tortuosity of the descending part of the arch. In eighteen cases reported, the inequality of the pulses was present in ten and not present in eight cases; in nine of the ten cases pulsation was more vigorous in the right than on the left side. Inequality of the pupils was present in three cases; in one of these it was probably due to some serious condition. Suprasternal pulsation was present in twelve cases and absent in six. Tracheal tugging of distinct downward character was present in eleven, and absent in seven cases. A systolic thrill was felt in the vessels of the neck, either with or without slight pressure, in nine cases, and it could not be elicited in nine cases. A systolic murmur usually transmitted into the vessels of the neck was present in eleven cases, but was not heard in seven cases. Twelve of the cases had dyspnœa; in one of these were physical signs of emphysema and chronic bronchitis; in the others it was probably due to the cardiac condition. Many of these patients were old, and nearly all of them had atheromatous arteries. Precordial pain was present in seven cases and was not complained of in eleven cases. In many of the cases complications in the form of valvular heart disease were present. In one case there was actually an aneurysm of the innominate artery. The degree of atheroma and the age of the patient also modified the symptoms, and the extent of the tortuosity must vary considerably in different cases.

The Transmission of Bovine Tuberculosis by Milk, with a Tabulation of Eighty-six Cases.—George M. Kober concludes: (1) Tuberculosis may be transmitted to man in milk from tuberculous cows. The danger cannot be measured by the actual number of recorded cases, but in part, at least, by the inoculation and feeding experiments and the accidental wound infections which occur; also by the prevalence of bovine tuberculosis and of the forms other than phthisis pulmonalis in man. The infectious qualities of milk are greatest when the udder is the seat of the lesions. Koch's assumption that human and bovine tuberculosis are distinct and that human tuberculosis cannot be conveyed to cattle appears to be disproved. The claim has been recently strengthened that there are two types of tubercle bacilli, the so-called bovine and human types, with certain morphological and biological differences; but also it has been shown that virulent cultures may be obtained from both types, and when inoculated into animals produce the disease in question. There should be further research to determine the frequency of primary intestinal and abdominal tuberculosis in all cases which come to autopsy, whether the child died from tuberculosis or not. Careful chemical analysis of the milk of tuberculous animals should be made with a view of determining the amount of phosphoric acid, since it seems probable from researches that the excess noted by the older chemists is the result of bacterial activity in the udder of the cow. In the meantime the pathologist need not reverse his opinion as to the identity of human and bovine tuberculosis, and the sanitarian has no reason to assume that the human subject is immune against infection with the bovine bacilli or is so slightly susceptible as to cause him to relax his efforts in preventive measures.

Primary Cancer of the Lung.—J. H. Musser writes that during the past eighteen months three cases of cancer of the lung have come under his observation. The case here specially reported was that of a man of forty-seven years. The patient complained of indigestion, sore throat at night, expectoration of mucus, dyspnœa on exertion, loss of flesh, and weakness. The sore throat was present only in the recumbent posture. A moderate cough would be attended by the welling up of large amounts of fluid. The fluid simply welled up from the pharynx and œsophagus. Headache was more or less constant, but only when the patient was stooping. Sleeplessness was very distressing. The pulse varied from 100 to 130 on exertion. Respiration varied from 28 to 32. There was no difference on the two sides. There were no signs at first in the lungs, except a slight pleural friction in the right axillary region. There was skodaic resonance over the right base. Later the lungs anteriorly were negative; posteriorly the resonance extended an inch lower on the left than on the right. The breath sounds were harsher on the right side, and vocal resonance was more distinct. There was a to-and-fro friction sound over the left base posteriorly. Breath sounds were quite indistinct in expiration. They were markedly rhoncous in inspiration, and attended by an abundance of small frictions on the right side. The breath sounds were feeble at the right base, with frictions. On the following day there were physical signs of pleuritis and diffused bronchitis. A few days later, bronchial breathing and moist râles were heard at both bases. The sputa showed three layers, as in bronchiectasis. The patient consulted the writer on December 12, and his death occurred on January 3. Autopsy revealed primary epithelial tumor of both lungs; metastasis in cervical, tracheal, and bronchial and retroperitoneal lymph nodes; fatty degeneration of liver, kidneys, and myocardium, chronic thickening of spermatic cord; cystic degeneration of the thyroid; chronic splenitis; and acute catarrhal bronchitis and tracheitis. Almost the entire extent of both lungs were apparently simultaneously involved. The tumor evidently originated from the epithelium of the alveoli. Most cases in the literature have arisen in the bronchial epithelium.—*University of Pennsylvania Medical Bulletin.*

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Sixteenth Annual Session, Held at Atlanta, Ga., December 15, 16, and 17, 1903.

J. Weslee Bovee, M.D., of Washington, D. C., President.

(Continued from page 36.)

The Progress of Ureteral Surgery.—Dr. J. Wesley Bovee of Washington, D. C., President of the Association, selected this title for his presidential address. After referring to the deaths of Drs. W. E. B. Davis, George J. Engelmann, and J. McFadden Gaston, he spoke on the surgery of the ureter, giving its history and present status. The treatment of ureteral calculi first claimed attention since the diagnosis and treatment of this condition were very much studied at the present time. The employment of the *x*-ray was the simplest procedure known for purposes of diagnosis, and were it accessible at all times and completely reliable, no other method would be comparatively valuable. Unfortunately, such conditions as calculous anuria might render a patient in a secluded place so ill that this method of investigation was necessarily precluded. Moreover, calculi might be of sufficient size to block the ureter and give no shadow in the radiograph. For this reason especially other plans of examination should be employed, although the necessity of constant manipulation of the ureter was a *sine quâ non* to dexterity in treating other conditions of this structure. Palpation would ever have its important position. Exploration was an important method in such investigations. Tubular calculi might escape discovery by this plan. The wax tipped bougie, suggested and used by Kelly, was especially sensitive, and no doubt if it touched a calculus it would receive a telltale impression. In the treatment of ureteral calculi the proper plan was extraperitoneal ureterolithotomy, as infected urine was usually associated with this condition and easily produced peritonitis, if permitted to come in contact with the peritoneum. If pus was not present, the establishment of ureterocutaneous fistula would seldom be necessary, though careful drainage of the wound would be advisable. This rule applied to every part of the duct. He was firmly convinced the ureteral wound should be made longitudinally whenever possible, and sutured after lithotomy. If much necrosis of the ureter was manifest, as had often resulted from the impaction of a calculus, each case should be treated according to the judgment of the surgeon, and such modifications as resection or exsection, with ureteroureteral anastomosis or ureterocystostomy might rarely be required. Frequently pyonephrosis accompanied calculous ureteritis. Incision and drainage, and probably nephrolithotomy, would be needed in addition. The routes employed depended upon the location of the calculus, the bladder, vagina, or loin being selected. He could only endorse the rectal route, as employed by Ceci, when examination revealed a calculus ulcerating into the rectum or threatening to do so.

For ureteral fistula nothing need be done unless obstruction of the duct below the fistulous opening existed. In such a case the caliber of the canal must be restored. Usually the fistula would then close spontaneously, although so much cicatricial tissue might be deposited about the opening as to prevent closure. Suture, or perhaps resection, might be required in that case. Dr. Bovee then referred to subcutaneous injury of the ureter, saying that no treatment was advisable unless evidence of extravasation of urine or of ureteral obstruction existed. For partial division of the ureter suturing should be applicable. Abnormal ureteral terminations of congenital origin might be corrected by ureterocystostomy, usually by the vaginal route. Fortunately in these cases the ureter was abnormally long, and therefore the difficulty was much less than was the same operation for other indications. The ureter might be removed in whole or in part for tumors, tuberculosis, and malignant disease. In 1899 he was able to collect, from literature, about twenty-four cases of partial or complete ureterectomy. Now the number had increased to nearly one hundred. In complete ureterectomy or nephroureterectomy in women probably the loin and vaginal incisions constituted the best plan. In his last case he separated the lower two inches through a vaginal incision, and then separated and withdrew the kidney and ureter by the loin route. This he believed to be the best of all.

For ureteritis the treatment had been largely of irrigation and topical applications. He had been disappointed in this work and had grave doubts of its being the best. Probably the violence done to the lower part of the ureter by this instrumentation counterbalanced the benefits. He had had a few cases of trigonitis that had come to him after ureteral irrigations were said to have been made. He had in consequence been led to speculate as to whether a non-alcoholic, non-nitrogenous diet with diuretics and rest in bed might not be superior treatment for simple ureteritis.

The Technique of the Vaginal Method.—Dr. J. Riddle Goffe of New York said in his own hands the scope of the operation, namely, the conditions to which it was applicable was steadily widening. It was no longer confined, on the one hand, to simple puncture and drainage, nor limited, on the other, to the radical operation of hysterectomy. All the intermediate procedures that were called for by the multifarious pathological conditions found in a woman's pelvis found their most direct route through the vagina. There were two vaginal incisions through which the pelvic cavity could be reached; one, posterior to the cervix into Douglas' pouch, and the other anterior to the cervix, separating the bladder from the uterus and opening up to view and touch the entire contents of the pelvis. The latter was the one which afforded the greater facilities for operative procedures, and the one which he depended upon almost exclusively. The posterior incision was frequently used in connection with it, to afford additional opportunity for the purpose simply of securing drainage, and in some cases for manipulation. The procedure was described. The simplest application of the vaginal method, and the one that probably commended itself most universally to the profession, was incision and drainage of pelvic abscesses. On general principles he believed all were ready to subscribe to the dictum that so far as the patient was concerned, any operation that could be as well done through the vagina as through the abdominal incision was better done along the vaginal route. The possibilities of this work would undoubtedly vary with individual experience, but the more experience he had, the broader became the field of application, until it seemed to him that any pathological condition that was confined to the true pelvis could be dealt with as satisfactorily, with as permanent results, and with far greater safety to the patient, through the vaginal incision than through the abdominal incision. The author's cases had embraced every variety of disease from simple retroversion, with or without adhesions, to prolapsed and cystic ovary, unilateral and bilateral salpingitis, ectopic gestation, fibroid tumors of the uterus and dermoid cysts. The method lent itself to every form of conservative work upon the uterus and its appendages that had been suggested in the trend of recent modern gynecology. The successful application of it required patience, experience, and skill, but when once the profession had been convinced of its superiority, he believed it would steadily and rapidly grow in favor and become the accepted method for the man who practised the specialty of gynecology.

Tuberculous Ostitis of the Knee.—Dr. A. R. Shands of Washington, D. C., said that the management of a case

of white swelling could be embraced in the terms immobilization and protection in any and all stages of the disease. The indication was to preserve the function of the joint as far as possible, to arrest the progress of the disease, to prevent and correct deformities. Immobilization and protection with the best hygienic surroundings and the best tonic treatment appropriate to the individual case would best accomplish the indication just mentioned. If the diagnosis was made early and this line of treatment faithfully carried out, a large percentage of cases would yield very favorable results, many recovering with little or no disability. When it became necessary to incise and drain a joint, it should be done thoroughly, and good drainage should be kept up just as long as there was any discharge. When the infection of the joint was due to an ostitis that was near the surface of the ends of the bone, often the diseased bone sloughed away, and when it could be easily located and curetted, most excellent results were obtained. A case was cited in point. The operation of excision of the knee should never be done in children, except in extreme cases, and even then the author believed that amputation would be best, for an artificial leg is more useful than such a leg as a child would have after excision.

Bilateral Diffuse Virginal Hypertrophy of the Breasts.—Dr. GEORGE BEN JOHNSTON of Richmond, Va., reported the case of a white girl, virgin, aged sixteen; four feet ten inches tall, weighing 112 pounds, who had this disease. The breasts hung from the chest wall at about the fourth rib and reached to a point just above the symphysis pubis; the nipple was flattened and stretched. The substance was soft and of similar consistence to that of a well-nourished multipara's breast; the glandular masses scattered throughout were distinctly palpable. The breasts were almost symmetrical, with the exception of a lobular division at the base of the left breast of the same general structure as the main tumor. Two small scars near the right nipple indicated the site of former abscesses. The anteroposterior circumference of the left breast was 19½ inches; the anteroposterior circumference of the right breast was 21½ inches; the superior inferior circumference of the left breast was 32 inches; and of the right, 31 inches. Operation was performed under ether anæsthesia, and occupied thirty-five minutes, the left breast being removed first, followed immediately by the right. The breast was held above the field of operation, and the amputation carried on as rapidly as the vessels could be caught by assistants. Healing was by primary intention, and the patient was up and about in six days.

The Differential Diagnosis of Syphilis and Cancer of the Vulva.—Dr. BARTON COOKE HIRST of Philadelphia read a paper on this subject. After referring briefly to the differential diagnosis of these two affections, the author reported the case of a woman, twenty-eight years of age, single, who had never been pregnant. She denied ever having led an immoral life, and the possibility of venereal infection. Ten years ago she was operated on in the Pennsylvania Hospital for hemorrhoids and fissure in ano. The wound of the operation did not heal properly. More than a year ago the patient noticed an ulcerated condition of the vulva, and a short time afterward incontinence of fæces, followed soon by incontinence of urine. For two years past there had been amenorrhœa. On a specular and digital examination, a fistula between the fossa navicularis and the rectum was discovered. The whole urethra was gone; there were three little tubercles at the neck of the bladder, these being all that was left of it. The vagina above the neck of the bladder was perfectly healthy. The cervix was normal, except that it was atrophic, as was the whole uterus. The case, at first sight, looked like an inoperable epithelioma of the vulva. It was pronounced to be so by one of the most experienced dermatologists in Philadelphia, to whom it was shown. But there was none of that extensive infiltration and elevation of the skin surfaces around the edges of the ulceration such as was seen in an example of extensive epithelioma of the vulva, considerably advanced, but not yet inoperable. Moreover, numerous pieces of tissue from different places in the ulcerated area showed nothing characteristic of cancer. There was everywhere the most extensive round-cell infiltration and necrosis of tissue. The microscopical study, as well as the macroscopical appearance, suggested syphilis in the ulcerated gummatous form as the most likely possibility, epithelioma being excluded. Accordingly the patient was put on specific treatment in spite of her negative history, and the entire absence anywhere in it upon her body of signs indicating an old syphilitic infection. The treatment was given up within a week, as the patient was severely ptyalised and could not endure large doses of potassium iodide. Lupus next suggested itself. On two separate occasions, under anæsthesia, twelve or fifteen pieces of diseased tissue were removed for microscopical examination. No tubercles nor bacilli could be discovered anywhere. Inoculations in animals were negative. The urine contained no tubercle bacilli. The bladder itself was healthy. There was a response to the tuberculin test, but the woman had a patch of consolidation in the apex of one lung. Meanwhile the patient was given *x*-ray treatments every other day for eight to ten minutes. Within three weeks the external ulceration was healed. The local appearance at that time showed great improvement. Two weeks later the rectovaginal fistula spontaneously closed under the continuance of the *x*-ray applications. Nothing remained of the original disease except the absence of the urethra and an elephantiasic condition of the labium majora. The former had been corrected by urethroplasty. He had not yet joined the new urethra to the opening in the bladder, so that the establishment of continence of urine was still doubtful, but he was quite hopeful of making the patient eventually entirely comfortable.

Symposium on Appendicitis.—Dr. GEORGE R. DEAN of Spartansburg, S. C., opened a discussion on appendicitis, saying there was not a surgeon who could tell in any given number of cases, in the beginning of the first attack, which ones would have severe attacks, and which light ones; which ones would die without operation and which would recover permanently; which ones would recover to have repeated attacks, or which ones would recover cripples but never have another attack. The surgeon should be called in all cases of appendicitis. He considered it a surgical disease, outside of the domain of the physician, and when it was once discovered there was only one proposition to be made, namely, to urge operation at the earliest possible moment.

Appendicitis and Its Relation to Pelvic Inflammations.—Dr. J. M. BALDY of Philadelphia, Pa., was able to appreciate the reasons, although not agreeing with them, of the class of surgeons who removed the vermiform appendix as a routine practice, as a prophylactic measure, but was unable to follow the reasoning of that class who adopted the practice of removal on the ground that the condition of adhesion implied appendicitis or future danger of this disease. Ninety-five per cent. of the mixed class were in origin cases of pelvic inflammatory disease, and the adhesion of the vermiform appendix was a mere coincidence due to inflammation of contiguous serous surfaces, as was so commonly the case of adhesion of intestines in pelvic inflammatory diseases. His experience had led him to differ with those gentlemen who held that appendicitis generated pelvic inflammatory disease, or that pelvic inflammatory disease caused appendicitis. The two diseases were rarely associated, and only then as a coincidence. He was firmly of the opinion that the one never causes the other. In all his experience he had not seen a single case in which, having found pus in a Fallopian tube, had he found pus in the involved vermiform appendix; nor had he found a perforating or gangrenous appendix in such a case. On the other hand,

where he had found a perforated or gangrenous vermiform appendix, or one which contained pus, either in its cavity or enclosed in its walls, had he ever noticed pus in a Fallopian tube or ovary. Should he meet with such a condition, it would appear to him that the two diseases existed as a coincidence independent of each other, as far as direct infection from one to the other was concerned.

Retroperitoneal Infection a Result of Appendicitis.—Dr. I. S. STONE of Washington, D. C., said that it was our plain duty in certain septic cases to investigate the retroperitoneal space with the same care as the cavity of the peritoneum. (1) One should consider every delayed case with anxiety lest there should be retroperitoneal infection. (2) One should be careful to give a guarded prognosis in every case of appendicitis ushered in by or complicated by chills or any symptoms of sepsis. (3) If operating in such cases one should consider retroperitoneal infection as already started, and act accordingly. The discovery and proper treatment of such infection was quite as important as the usual intraperitoneal technique. In view of the possibilities of retroperitoneal infection, the surgeon assumed great responsibility by devising non-intervention in appendicitis, and while one would often advise delay, when he believed the lesions were strictly intraperitoneal, yet it would appear to the writer that such a course was unsafe and should be condemned when there was reason to fear complications.

Short Incision in Appendicitis.—Dr. ROBERT T. MORRIS of New York said the beginner in surgery was inclined to make incisions that were too short, rendering his work more difficult and very likely incomplete. With the establishment of confidence in his resources, the tendency was to make freer and bolder incisions. The surgeon could not do good work, particularly in abdominal surgery, if he began his work with incisions that were too short. He could not do the best work if he continued to make incisions that were too bold or too free. After one had acquired a certain amount of skill in technique, he could return to the shorter incisions, which would allow the patient to escape with the least possible attack of incision. Even a bear had been known to die from too much incision, and in dealing with patients the incision was of some consequence to them. With long incisions there was more shock; more adhesions, (1) because the exposure of the peritoneum through a long incision excited greater inflammatory reaction, and this resulted in more peritoneal adhesions, which must be disposed of, or which might remain to make the patient life-long trouble. (2) The longer the incison, the greater the danger of infection from the aërial bacteria. With long incisions the patient's general resistance was interfered with. He would make this statement, however, that the surgeon should make as long an incision as he felt was necessary, and by no means be guided by the idea that he was to conform to any length of incision, the idea being that if one could allow the patient to escape with a mild attack of incision, he should do so.

The Significance of and Management of Paralysis of the Bowel.—Dr. GEO. S. BROWN of Birmingham, Ala., emphasized the views held by the surgeons of the past generation, that paralysis of the bowel in the presence of inflammation of the peritoneum was to be regarded, not as a pathological condition to be combated, but rather as nature's way of allowing the plastic exudate to form adhesions, the use of which was to confine the infection to as limited a field as possible. He held that it was not the paralysis, but the overdistention of the bowel, that should be fought. By following the plan of keeping the upper uninflamed portion of the bowel quiet, until the inflammation subsided, rather than attempting the difficult or impossible feat of waking up the inflamed and paralyzed portion by the use of purgatives, he believed many, or the majority, of the worst cases of diffuse peritonitis with which the surgeon had to deal might be cured. This rest treatment should be applied after the offending appendix or tube had been removed, and the infected site properly treated and drained. It seemed to him that if the Ochsner plan of treatment would tide over a patient with a gangrenous appendix, such a patient could have a much better chance if that appendix were removed, and to the Ochsner treatment were added the tight abdominal binder with water to relieve thirst and wash out the stomach, if there was vomiting, together with opium *ad libitum*, to relieve pain and keep down peristalsis. He believed that many patients died with all the symptoms of general peritonitis following operations for appendicitis in which an autopsy would show that the inflammation had been walled off, and that death was really due to the activity of the upper bowel, due to the presence of food or purgative, which, being unable to pass the lower paralyzed portion, set up a return wave of peristalsis causing regurgitant vomiting and death from exhaustion and sepsis. He related two cases in point. Both patients had high fever, great distention, and gulping fecal vomit, and the autopsies showed that neither had general peritonitis. One of these patients had been operated upon, the other had not, but both had been given large doses of purgatives. In a total experience of ninety cases of appendicitis he had sixty-six pus cases, twenty-four of which had been treated by the plan of starvation, except as to water, prolonged irrigation of the stomach before leaving the table, a tight abdominal binder and opium. Eighteen of these patients had more or less diffuse peritonitis, and twelve of these were so severe that they had to be extensively disemboweled in order that adhesions could be broken up and septic material wiped away. Two of these only died. These might have recovered had they been tided over without operation, but as they were both *in extremis* at the time, probably the only thing saved would have been the reputation of the surgeon. Of five other deaths occurring in the ninety cases, two were due to subdiaphragmatic abscess rupturing into the lung, one to regurgitant vomiting, due to the presence of a large quantity of castor oil in the bowel which was not washed out, and two were early cases in which abscesses that had already set up a diffuse peritonitis were merely incised.

Septic Thrombosis of the Femoral Vein Following Influenza.—Dr. D. F. TALLEY of Birmingham, Ala., reported a case of septic thrombosis due presumably to influenza, from which the patient was recovering when the phlebitic trouble arose.

Five Successful Laparotomies for Gunshot Wounds of Abdominal Viscera.—Dr. ROBERT W. JOHNSON of Baltimore, Md., read a paper with this title, in which he reported five cases. The first was one of gunshot wound of the stomach and liver; laparotomy, with recovery. Second, a gunshot wound of the liver; laparotomy, recovery. Third, gunshot wound of the liver; laparotomy; recovery. Fourth, gunshot wound of intestine; laparotomy, recovery. The fifth case was one of gunshot wound of the intestines, in which there were seventeen perforations of the gut, eleven of the mesentery. The patient was a colored man, aged seventeen. While watching an election row he was shot in the abdomen. When put on the table he presented the appearance of a strong, well-developed negro, composed in manner, but suffering from proound shock. There was no pulse at the wrist, and collapse seemed imminent. Salt solution was injected into the thighs and strychnine given hypodermically. A wound from a thirty-two caliber ball was found in the left side just above Poupart's ligament, which, after washing, was found to go directly into the abdominal cavity. A median incision was made below the umbilicus and the belly found to be full of blood. Through this incision the gut was drawn out on to warm towels and seventeen perforations of the small intestine, and eleven of the mesentery, were successfully closed

by silk Lembert sutures. Patient had no setback after the operation, and was discharged well three weeks after injury was received.

Cases of Intestinal Obstruction Treated by Resection.—Dr. W. H. Doughty, Jr., of Augusta, Ga., reported three successful cases of resection of intestine for obstruction due to gangrenous umbilica hernia, volvulus, and intussusception respectively. He presented these cases briefly as a contribution to the statistics of an operation, the mortality of which was very high. One of the cases was rather unique, so far as the author knew, in that the strangulated loop of intestine in the hernia was a part of a greater segment which had been strangulated by volvulus. It was likely that the descent of the herniated coil took place shortly after the occurrence of the volvulus, and its strangulation was occasioned by the congestion which followed the latter. The almost invariable fatality which attended the operation he attributed to the toxæmia that was induced by gangrene of the intussusceptum. In one case, however, which he outlined, in spite of the unmistakably gangrenous patches upon the intussuscipiens and involving even the mesentery, the patient, though far from being in a satisfactorv condition, stood the operation fairly well, rallied promptly from the depression which attended it, and recovered without interruption.

Free Growths in the Tunica Vaginalis.—Dr. Edward A. Balloch of Washington, D. C., reported the case of a colored boy, sixteen years of age, who came under his care in December, 1902. Family and personal history threw no light on the case. There was no history of injury. Present trouble began eight years before, as an enlargement in the upper part of the right of the scrotum, which continued to grow painlessly from that time onward. Examination showed a scrotum reaching nearly to the knees and measuring twenty-one inches in circumference at its largest point. Both testicles and both cords could be made out and felt normal as to size, shape, and consistence. There was no fluid in the scrotum, but a peculiar gelatinous, flabby feeling of the scrotal tissue. Three separate tumors were felt in the right side of the scrotum. The growths were freely movable in relation to cord, testis, and scrotal tissue. The diagnosis of fibroid growths in the tunica vaginalis was based partly on the history of a slow, painless growth, and absence of ulceration and fistulæ, excluding cancer, syphilis, and tuberculosis, and partly on the physical characteristics of the growths, together with a cheloid behind the right ear which was interpreted as indicating a tendency to fibromatosis in the patient. Operation, December 15, 1902, showed the tunica greatly enlarged and thickened, and converted into a gelatinous mass. The upper tumor ran into the inguinal canal and was attached there by a pedicle. The other two showed no distinct points of attachment. All the tumors were enucleated and the thickened tunic removed. The testicle was removed accidentally in dissecting out the tunica. The tumors weighed thirty-eight ounces, and the tunica twenty ounces. The specimens were shown. The report of the pathologist showed that the growths were soft fibromata, with areas of fatty and myxomatous degenerations. The testicle also showed areas of beginning myxomatous degeneration. The pathology of the condition was considered briefly, the conclusion being reached that the growths had their origin in the subserous connective tissue. Examination of the literature showed but one case at all resembling the one reported, although there were several reports of minute fibrous growths on the tunic following hydrocele treated by the injection of iodine.

Extrauterine Pregnancy.—Dr. T. J. Crofford of Memphis, Tenn., reported a case and exhibited a specimen in which the gestation sac was so thoroughly developed and so strong, that it was enucleated without the loss of any blood. The sac was completely intact all around the fœtus. The operation was performed before the class. The speaker supposed it to be a parovarian cyst. After the specimen was removed, it was thrown upon the floor. When the patient was put to bed, the sac was slit open and out came the fœtus. When the abdomen was opened in this case, the head of the cæcum was found in front and adherent to the anterior abdominal wall. It was found necessary to remove the appendix.

Colloid Carcinoma of the Rectum with Excision by the Combined Vaginal and Inguinal Routes.—Dr. J. Horace Whitacre of Cincinnati, Ohio, reported a case of colloid carcinoma of the rectum which presented unusual pathological and clinical features. After detailing a complete history of the case and describing the operation, the author stated that his chief reason for presenting the case was the unusual nature of the primary tumor. He had never before seen a carcinomatous tumor of the bowel which had developed as a hard, uniform thickening of the entire circumference of the tube. The tumor involved the wall of the rectum to almost a uniform degree for six inches of its length, and the organ was transformed into a tube that might very well be compared to a flattened lead pipe with very thick walls. The tube was very rigid and non-collapsible when in a fresh state. The lumen of the tube was unfortunately firmly packed with gauze before it was placed in Kaiserling's preservative fluid, and had been thereby dilated to almost twice its actual size during life. A second point of interest was the strong naked eye resemblance to tuberculosis. The minute bodies which were scattered over the pelvic peritoneum could not be differentiated from miliary tubercles. Large caseous lymph nodes were found in the hollow of the sacrum. The great predominance of fibrous tissue, the uniform involvement of a long segment of the bowel, and the appearance of minute nodules resembling miliary tubercles in the primary tumor of the rectum all spoke for hyperplastic tuberculosis of the bowel. A third point worthy of mention was the exceedingly rapid development of the solidly carcinomatous ovarian tumors from half a dozen minute miliary metastases on the peritoneal surfaces of each. These tumors were friable and almost jellylike, as were all of the metastases, whereas the original tumor was as hard as cartilage.

Pneumatic Rubber Suit.—Dr. George W. Crile of Cleveland, Ohio, said that the pneumatic rubber suit was constructed of a double layer of specially made rubber, which, when inflated, exerted a uniform pressure upon the surface, constituting an artificial peripheral resistance. It was so constructed that one or more limbs or the abdomen might separately or in combination be subjected to pressure by inflation by means of a bicycle pump. The air valves were so adjusted that the rate of decompression might be completely controlled. The effect of the suit upon the blood-pressure might be checked by means of a sphygnomonometer. The general blood-pressure might be varied at will within a range of 25 to 75 mm. of mercury. The rise had been sustained as long as twelve hours. In operations upon the head and neck, which were likely to be attended by dangerous shock and collapse, the pneumatic suit was put on the patient prior to operation. By inflation and deflation the blood-pressure might, within certain limits, in the heaviest operations, be maintained at a given level. In a laryngectomy, with extensive resection of lymphatic-bearing tissue of the neck, moderate shock developed. The blood-pressure was raised by means of the rubber suit, which soon sprung a leak; a marked fall in the blood-pressure following. During the experimental stage, the influence of the pneumatic suit upon the blood-pressure was strikingly demonstrated in a pulseless case in which the blood-pressure was raised to 110 mm. Other cases were reported, showing the value of the pneumatic rubber suit in cases of shock and collapse.

Resuscitation of Animals Apparently Dead.—Dr. Crile also read a short paper on this subject, giving a summary of experimental data. When asphyxia caused failure of

the heart and respiration, vigorous artificial respiration usually restored their function when administered within a few seconds. It was effective in an inverse ratio to the time that had elapsed; it was rarely effective after forty seconds. By the addition of saline infusion a larger proportion of animals could be resuscitated after the lapse of a little longer time. Rhythmic pressure upon the heart, either through the thorax by pressure upon the ribs over the heart or direct pressure within the thorax was also an aid. The effect of the traumatism to the heart by the direct method partially counterbalanced the benefit from this measure. Nitroglycerin, alcohol, and digitalis were useless; rapidly alternating the posture, head up, then head down, was not effective. Suspending the animal head down and making rhythmic pressure upon the heart was an effective method. This method gave the brain the advantage of gravity; it provided a moderate artificial circulation as well as respiration. It could be promptly applied. The addition of this saline infusion increased the effectiveness of the method. Animals apparently dead for periods up to fifteen minutes were resuscitated by the combined effect of artificial respiration, rhythmic pressure upon the heart, and the infusion of adrenalin. When the blood-pressure had risen to 30 or more mm. Hg., the heart began to beat and the blood-pressure was rapidly restored. The return of respiration was signaled by a short, almost imperceptible movement of the diaphragm, the respiratory action becoming gradually stronger and more frequent. The conjunctival reflex returned early. Some of the experiments failed on account of too great elevation of the adrenalin bottle; some on account of an overdose of adrenalin; several were only partially successful, owing to the great dilution of the adrenalin. Adrenalin, when injected directly into the chamber or into the wall of the heart, caused fibrillar contractions, after which the heart could not be resuscitated. After final cessation of the heart, by employing manual compression of the heart and infusing adrenalin, the blood-pressure could be raised even higher than the normal. Respiration in some instances was partially restored. Experiments in which saline infusion was substituted for adrenalin, and which were unsuccessful, were promptly successful on adding adrenalin. In a patient with crushed skull, and whose heart had ceased beating for nine minutes, resuscitation of the heart for thirty-one minutes was made by this method. During the operation for the elevation of the depressed bone, the patient moved his head. Another patient apparently dead from a severe crushing of the base of the skull was partially resuscitated twenty-four minutes after the apparent death. The proofs of the apparent death were absence of respiration, absence of heart sound on a stethoscopic auscultation, and, as a final proof, on opening the jugular vein there was absolutely no circulation. In this case the blood-pressure rose to 80 mm. at one time; voluntary respiration appeared. These evidences of vital action continued for thirty-four minutes.

Officers for the Ensuing Year.—The following officers were elected: *President*, Dr. Floyd W. McRae, Atlanta, Ga.; *First Vice-President*, Dr. Geo. S. Brown, Birmingham, Ala.; *Second Vice-President*, Dr. J. Shelton Horsley, Richmond, Va.; *Treasurer*, Dr. Chas. M. Rosser, Dallas, Tex.; *Secretary*, Dr. W. D. Haggard, Nashville, Tenn.

Birmingham, Ala., was selected as the place for holding the next annual meeting; time, December 13, 14, and 15, 1904.

Dr. John D. S. Davis of Birmingham was selected as the Chairman of the Committee of Arrangements.

The Council made a report to the effect, that the former action of the association in appropriating two thousand dollars, to a memorial in Birmingham, consisting of a ward bearing the name of the association in the City Hospital of Birmingham, be rescinded, and that in lieu thereof two thousand dollars be appropriated to the erection of a monument to the memory of Dr. W. E. B. Davis in Birmingham.

The report of the Council was adopted.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Eighty-third Regular Meeting, Held on November 6, 1903.

Dr. CHARLES STEDMAN BULL, PRESIDENT, IN THE CHAIR.

Neural Injection of Osmic Acid for Facial Tic.—Dr. ROBERT ABBE presented a young man who had first come under his observation two years ago. The patient was then suffering from a severe form of facial neuralgia which involved the middle branch of the fifth nerve on the left side. As a radical operation was refused by the patient, an inch and one-half of the nerve was resected by raising the cheek after a free incision of the lip. This operation gave immediate and permanent relief; but a few weeks ago the patient began to suffer from similar pain affecting the supraorbital branch of the nerve. The pain was shooting in character, like an electric shock, recurring about once every ten minutes during the day, and occasionally it awoke him at night. It radiated upward from the left eye and there was marked tenderness of the entire scalp. As the patient still objected to an intracranial neurectomy, Dr. Abbe said he intended to resort to the neural injection of osmic acid, as had been successfully practised by Bennett. The nerve was exposed through a small incision along the upper margin of the eyebrow, and perhaps five drops of a 1½ per cent. solution of osmic acid was injected into the substance of the nerve. Dr. Abbe said he would report subsequently as to the result of the procedure.

Dr. CHARLES STEDMAN BULL called attention to the fact that the destruction of the supraorbital branch of the fifth nerve rendered the cornea non-sensitive and very liable to injury from the effects of dust or cold air. After the radical operation for facial neuralgia (removal of the Gasserian ganglion), superficial ulceration of the cornea was not an infrequent occurrence. It could be obviated by temporarily stitching together the edges of the lids.

Dr. Abbe said he understood that if the cornea was properly protected from dust and injury for a few days after these operations, it would be able to take care of itself.

The Value of the Thomas Sling in the Treatment of Fractures at the Elbow-joint.—Dr. VIRGIL P. GIBNEY presented a boy who had sustained a fracture of the internal condyle of the right elbow. When he entered the Hospital for the Ruptured and Crippled, three weeks later, motion at the joint was much limited. Massage was first ordered, and then the arm was put up in a Thomas sling and kept in that position for several weeks. Over four months had elapsed since the receipt of the injury, and the boy now had practically a perfect elbow. Flexion, extension, pronation, and supination were normal, and the condyle seemed to be in fairly good position. The patient was shown to illustrate the value of the Thomas sling in the treatment of these cases

A Case for Diagnosis.—Dr. GIBNEY showed a boy of eight years, who first came under his observation three years ago. No history was obtainable. Examination revealed an ossification of all the tissues of the right leg underneath the skin, extending from the pelvis to the internal malleolus. The condition was apparently congenital. All the joints of the leg were involved in the process and were immovable. Dr. Gibney said the condition did not correspond in all respects to a myositis ossificans, and he was inclined to attribute it to a congenital defect of the lymphatic system of the leg. The boy was otherwise in good health.

A Case of Walrus Fin.—Dr. GIBNEY presented a boy with that peculiar condition of the extremities which has

been designated as "walrus fin." Both feet were inverted, and the hands were pronated and could not be brought into a position of supination. There was also a congenital dislocation of one hip. The condition was attributed to a failure of development of the joints.

A Case of Extreme Rickets.—Dr. GIBNEY also showed a female child, four and one-half years old, with marked deformity of the joints (especially of the wrists), pot belly, curvature of the femora, and other evidences of extreme rickets. The bones, however, were apparently firm and did not fracture easily, as in some of these cases. In one instance coming under his observation the bones of the extremities had suffered such numerous fractures from very slight injuries that the resulting shortening made the patient's body appear preternaturally long and his limbs preternaturally short.

The Management of Fractures Involving Joints.—Dr. VIRGIL P. GIBNEY read this paper (see page 43).

Dr. ABBE said it had not been his experience that it was easier to correct faulty flexion than extension after fracture at the elbow-joint. He was in favor of putting up these cases in a flexed position, no matter what the character of the fracture might be, and keeping the limb at a somewhat acute angle. It was to this principle that he attributed the value of the Thomas bandage. Extension would usually be fully restored in the course of time. He did not favor passive motion after fractures. In the treatment of fractures involving the neck of the femur he considered the application of plaster-of-Paris the most comfortable and serviceable method; it rendered the patient more manageable in bed and obviated the bed sores which were so common in that class of cases, especially in old people who were treated with Buck's extension.

Dr. ROBERT F. WEIR said he regarded extreme flexion as the important point in the treatment of most of the fractures involving the elbow. We should try to get the arm up as far as possible in order to hold fragments in the best possible position and avoid future disablement. In the treatment of fractures of the leg, on the contrary, flexion should be avoided: the limb should be kept as straight as possible. In the upper extremity retention of motion less than a right angle was to be kept in mind. If a fracture of the elbow-joint was attended by considerable displacement of the fragments, as disclosed by the *x*-rays or otherwise, and efforts to replace them by manipulation proved unsuccessful, Dr. Weir, said he did not hesitate, after a week or ten days, to open the joint and replace and suture the fragments in their proper position, with chromicized catgut. The arm should then be strongly flexed and held in that position. The speaker said he fully appreciated the value of plaster-of-Paris in the treatment of fractures: it could be employed in the treatment of all fractures, with the exception, perhaps, of those involving the femur in its shaft.

Dr. Gibney, in closing, said he agreed with Drs Abbe and Weir that the treatment of fractures of the elbow-joint by flexion had many points in its favor. He recently saw several cases, however, in which that method had resulted in considerable interference with subsequent extension of the limb. In a paper published by Gillette and Brimhall (*St. Paul Medical Journal*, August, 1902), the authors had brought up this point and had mentioned as one of the advantages of the extended position that it preserved intact the fossa of the elbow, serving also as a splint for the condyles. Dr. Gibney said he was thoroughly in favor of the open method of treatment in certain cases of fracture at the elbow-joint.

Result of a New Method of Creating a Vagina in a Case of Congenital Absence.—Dr. ROBERT ABBE reported on this case, which was first presented to the society in 1898, and a complete report of the operation was published in the MEDICAL RECORD in the issue of December 10 of that year. The patient was a young woman of twenty-one years, who, after becoming engaged to be married, confided to her sister that she had never menstruated. An examination showed that the external genitalia were perfect, excepting that from the meatus urinarius to the perineum was a blank wall. A rectal examination revealed an entire absence of uterus and ovaries. The following operation was carefully planned and carried out: For several days the alimentary canal was made as empty as possible. A crescentic cut was made across the interlabial space, with concavity upward, thus getting a little shelf of mucous membrane below the urethra to divert escaping urine. By blunt dissection a free cellular space was readily created between the bladder and the rectum, to the depth of five inches. This was temporarily packed with sterile gauze to check oozing. Thiersch skin grafts were then cut from the thigh, sufficient to cover an ample plug made thus: A thin French rubber pouch, such as can be obtained at drug stores, was sterilized by boiling and stuffing with long strips of iodoform gauze to its full capacity. Upon this the skin grafts were spread with their wet sides outward and edges freely overlapping. (The method of transferring the grafts after floating them on rubber tissue immersed in salt solution was devised by me, and has been continually used for the past eight years.) Numerous small punctures had been previously made in the rubber bag after stuffing, so that the gauze contents would receive any discharge lurking about. A piece of rubber tubing, the size of one's little finger, wrapped loosely about with iodoform gauze, was now inserted into the rectum, with a view of permitting free exit of gas during the subsequent days of enforced constipation. Finally the graft-covered form was carefully passed into the new vaginal space, the walls of which were held apart by three deep retractors, which, on removal, allowed the fresh surfaces to come into closest contact with the wet surface of the grafts. To prevent the plug from being in the slightest displaced, two silkworm-gut stitches were passed across the vulva, transfixing the gauze-packed tampon, and tied over iodoform plugs at either side, as seen in the illustration. The urine was drawn every eight hours for a week with such precaution that no cystitis resulted. The bowels were confined for ten days, without the slightest discomfort to the patient. Light diet was given. No febrile reaction whatever followed.

On the tenth day, when the packing was removed, it was seen that the grafts had taken universally, and that a newly-lined cavity had been created four and one-half inches in depth. Ten weeks after the operation the patient married. When she began to go about, the gravitation of the abdominal contents tended to shorten the vaginal canal, and it was found necessary for her to wear a vaginal plug, part of every day at least. Several varieties were tried, but nothing was so comfortable as a good-sized wax candle, smoothed and rounded, and kept in by a T-bandage. Omissions of one or two weeks allowed considerable shrinkage, but the renewal of the plug overcame it.

When the patient called on Dr. Abbe, a few days ago, she stated that during the four years of her married life the canal had remained competent. An examination showed that inevitable stenosis, by cicatricial contraction, had reduced the artificial vagina to two and one-half inches in depth, but as it was made more than ample in the original design, it remained to-day a practical and competent canal.

Dr. GEORGE L. PEABODY said that many years ago he had assisted a general surgeon in a similar case. As in Dr. Abbe's case, the external genitalia were perfect, but the vagina was entirely wanting. A good-sized opening was made between the bladder and the rectum, and into this a vaginal glass plug was inserted. No skin grafting was done, and the operation proved unsatisfactory, as the opening soon closed by cicatricial contraction, in spite of systematic attempts to keep it open.

Dr. CLEMENT CLEVELAND thought thes ecases of congenital absence of the vagina were very rare. He recalled one instance which was very similar to that mentioned by Dr. Peabody, but he was unable to say what the ultimate result of the operation had been.

Dr. WEIR said the method of skin-grafting described by Dr. Abbe might also prove serviceable in the treatment of cicatricial strictures of the rectum. The successful application of a skin-graft, after the division of such a stricture, would be a great help. The speaker said he had attempted this in three cases. In one, in which he took the skin from a distant part of the body, the result was a failure. In the other two cases he took a long strip of skin from the buttock and twisted it into the rectum without completely severing its external attachment. In one of these cases the procedure was a partial success: in the other, a complete failure.

Dr. Abbe, in reply to a question, said the dissection between the bladder and rectum was made with comparative ease. It was carried down to the subperitoneal layer

New Instruments.

TONGUE FORCEPS.

BY LUCIEN L. MINER,
NEW YORK.
MEDICAL STUDENT AT COLUMBIA UNIVERSITY.

MOST tongue forceps in use to-day have serious disadvantages in that they bruise or puncture the tongue. An anæsthetist is often bothered by a rebellious tongue that persistently falls back, blocking the larynx, yet he hesitates to apply tongue forceps, and relieves the condition as best he can by pushing the jaw forward. Sometimes he is forced to secure the tongue by forceps, spike, or needle and thread, none of which is a very refined method. This is my excuse for devising the instrument here described.

The cut explains itself. The forceps, by means of a central fenestrum and a side slot, secures two pieces of gauze which grasp the tongue gently but firmly. Clean gauze can be applied for each patient.

To prove that the tongue is not bruised, I have tried it on persons not under an anæsthetic and have found that the tongue can be securely held without exerting pressure enough to cause any pain whatever.

The forceps can be advantageously used in minor throat operations under cocaine, in a difficult case of intubation. It is especially useful in abdominal work for holding the intestines without danger of trauma.

I am greatly indebted to Mr. Ford, the instrument maker, for valuable assistance in changing the original idea of a bulky double set of forceps to the present simple device.

Radiographing Criminals.—Röntgen rays will soon be made use of by the Paris police for the identification of criminals. Some 16,000 plates have already been collected, chiefly from the hospitals. Of course, all these do not represent portions of the internal anatomy of criminals. But the police go on the principal that people who have not broken the law yet may do so some day. These plates are, accordingly, being classified after the method invented by M. Bertillon. It is proposed that in future all convicted persons shall be radiographed as they are now "anthropometrized."—*London Daily Telegraph.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE HOSPITAL FORMULARY OF THE DEPARTMENT OF PUBLIC CHARITIES AND THE DEPARTMENT OF BELLEVUE AND ALLIED HOSPITALS OF THE CITY OF NEW YORK. W. E. DREYFUS, A.B., Ph.D., Editor. Sixth revised edition, 8vo, 160 pages. New York, 1903.

A NON-SURGICAL TREATISE OF DISEASES OF THE PROSTATE GLAND AND ADNEXA. By GEORGE WHITFIELD OVERALL, A.B., M.D. 12mo, 217 pages. Rowe Publishing Company, 1312-34 E. Washington St., Chicago Ill. Illustrated.

HANDBOOK OF DISEASES OF THE EAR. By RICHARD LAKE, F.R.C.S. With three colored plates. 12mo, 232 pages. William Wood & Co., New York.

Therapeutic Hints.

The Relations between Peritoneal Adhesions and the Functionating Uterus.—Ch. B. Reed finds that many adhesions are undoubtedly destroyed by the growth of uterus in pregnancy, but the rupture of the same may be attended with fatal hemorrhage.

Adhesions between the movable organs of the abdomen and the functionating uterus are only rarely a source of danger or cause of death. Where adhesions are protecting the peritoneal cavity from pus pockets, either appendicular or tubal, and pregnancy supervenes, a condition of extreme danger is present. The pus should be evacuated as soon as possible after the diagnosis is made without reference to the pregnancy.—*The Chicago Medical Recorder.*

Methylene Blue in Diarrhœa.—Combemale of Lille strongly recommends the use of this drug in all forms of rebellious diarrhœa. He thinks it is particularly indicated in infectious cases, such as those due to typhoid fever, etc. The dose is one grain three times a day.

—*Medical Press.*

Opacity of the Cornea.—Mazel of Marseilles recommends a solution of benzoate of lithium (5 to 15 gr. in ℥ii · p. aqua) to be instilled into the eye t. i. d.—He reports several patients successfully treated with this solution.

—*Medical Press.*

The Extraction of Foreign Bodies from the Ear.—Use a soft rubber tube, about the length of a cigarette, and of the proper size to be introduced into the ear. The end of the tube is dipped in paraffin, and pushed into the canal until it comes in contact with the foreign body, whereupon the operator, applying his mouth to the free end aspirates forcibly, at the same time throwing back his head. Except in cases of angular bodies of irregular contour, this method is usually attended by success, the body coming away with the tube.—*Medical Press.*

Carcinoma of the Bile-ducts.—On account of the deep situation of the bile ducts and the great difficulty in making an early diagnosis, surgery will probably never accomplish very much. If an operation is carried out sufficiently early, while the process is confined to the duct, it may be successful. If the disease be in the cystic duct, this duct, with the gall-bladder, should be removed. If the adjacent portion of the liver is implicated, a V-shaped piece of the liver may be excised. If the common bile duct is implicated a portion may be excised, the ends united with sutures, and the fundus of the gall-bladder attached to the wound or to the intestine. If the common bile duct be implicated and the growth cannot be removed, an anastomosis may be made between the fundus of the gall-bladder and the duodenum—cholecystenterostomy. If the growth is situated in the head of the pancreas and involves the common bile duct, excision is impracticable and a cholecystenterostomy should be done.—A. Hamilton Levings in the *Clinical Review.*

Physostigma.—Hare thinks that physostigma is a valuable drug in atony of the bladder or intestines, and in catarrh of the bowels; also, when combined with nux vomica, in gastric and intestinal dilation.

Fetid Breath.—

℞ Inf. sage 250.0
Glycerin, pure 30.0
Tinct. myrrh .....
Tinct. lavender ..... ää 12.0
Laborraque's solution 30.0

M. et S. Mouth wash, as required.

When due to gastric fermentation, wood charcoal in dose of ten grains every three hours. —Campbell.

To remove vegetations from the external genitals salicylic acid is an excellent remedy. Dissolve half a drachm in an ounce of acetic acid, and apply to parts with a camel's hair brush.—*The Southern Clinic.*

In Acute Laryngitis.—Full doses of sodium bromide should be given, and an embrocation of oil of amber, one part, to olive oil, three parts, should be rubbed in thoroughly over the larynx.—*The Southern Clinic.*

Epilepsy.—Dr. James Taylor does not believe that belladonna is of much effect in the treatment of epilepsy. He has found digitalis of much use, especially in those cases showing nocturnal attacks and in instances in which the patients have cold and cyanosed extremities.

—*Clinical Journal.*

Acute Bronchitis in Infants.—J. B. Norman speaks very highly of apomorphine as an expectorant in these cases. He gives $\frac{1}{600}$ grain every two hours. He has observed great benefit from combining strychnine with the apomorphine. —*Kansas City Medical Index-Lancet.*

Pruritus.—

℞ Chloral hydrate ..... 1 part.
Camphorated oil (1 in 10) ..... 10 parts.
Lanolin ..... 90 parts.

Or,

℞ Zinc oxide ..... } Equal parts.
Chalk ..... }
Camphorated oil ..... }
Lime water ..... }

—Leredde.

Urticaria.—

℞ Hydrarg. chloridi corrosiv. ..... gr. iss.
Chloroformi ..... ♏. xx.
Glycerini ..... fl. ℥ii.
Aquæ rosæ ..... fl. ℥vi.

M. ft. lotio: S. external use.

—Burgess.

Pruritus Ani.—

℞ Ext. conii ..... ℥ii.
Ungt. stramonii .....
Lanolini ..... ää ℥i.

M. Sig: Apply at bedtime and before stools.

—Tuttle.

Squibbs' Cholera Mixture.—

℞ Tinct. opii .....
Tinct. capsici .....
Spts. camphoræ ..... ää ℥i.
Chloroformi ..... ℥iii.
Alcoholis ..... q. s. ad. ℥v.

M. Dose, 20 to 40 minims.

Phosphorus for Hoarseness.—A very valuable drug for chronic hoarseness and loss of voice, is phosphorus in small, frequently repeated doses.

—*Pennsylvania Medical Journal.*

Chronic Gout.—

℞ Ext. colchici radicis .....
Ext. aloe .....
Pulv. ipecacuanhæ .....
Hydrarg. chloridi mitis ..... ää gr. i.
Ext. nucis vomicæ ..... gr. ¼

M. For one pill. S.: One every 3 or 4 hours until purgation ensues.

—A. L. Loomis.

Or,

℞ Magnesii sulph ..... gr. ii.
Potassii bicarb ..... gr. xv.
Tinct. colchici seminis ..... ♏ x.
Infus. buchu ..... fl. ℥i.

Ft. haustus. S.: To be taken every 4 to 6 hours, followed by a large draught of water.

—Fothergill.

Dry Scaly Eczema of the Auricle or External Meatus.—

℞ Hydrarg. oxid. rub .....
Hydrarg. ammoniati ..... ää gr. vi.
Adipis benzoat ..... ℥i.
Ol. olivæ ..... ℥ii.

Apply on cotton plugs.

—Barr.

Chloroform as a Teniafuge.—According to Dr. Leger, in the *Medical Press*, chloroform is as efficacious in the treatment of tapeworm as male fern, etc. He uses the following mixture:

Chloroformi ..... ℥i.
Syrupi ..... ℥i.
Aquæ ..... ℥iv.

A quarter of this is to be taken every three-quarters of an hour, and before the last dose a purgative of castor oil or tincture of jalap is given.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 2, 1904:

	Cases.	Deaths.
Measles	584	15
Diphtheria and croup	461	59
Scarlet fever	345	23
Smallpox	1	1
Varicella	97	...
Tuberculosis	229	177
Typhoid fever	36	10
Cerebrospinal meningitis	...	3

Arguments in Support of the Army Canteen.—The following report of the Committee on the Army Canteen was read by Dr. George M. Kober, Chairman, at the recent meeting of the American Public Health Association:

"(1) Your committee is aware of the fact that beverages containing alcohol are an accessory food of value only when it becomes necessary to increase temporarily the elasticity of mind and body and a desire and capacity for work, and that the subsequent depressing effects and the baneful influence of their misuse requires great care in its employment, especially when rest, proper food and some of the alkaloidal beverages, like coffee, tea, cocoa, and stimulants, like meat broths and soups, may accomplish the same purpose, and their sale as a substitute should be encouraged.

"(2) In spite of the fact that beer drinking, viewed in the abstract, is unproductive of good, your committee believes that its sale in canteens, under rational and comprehensive regulations, rather than its total prohibition, will subserve the best interest of scientific temperance, because so long as human nature is weak and the masses are not properly educated, the substitution of a lesser evil under military control appears not only justifiable, but will in the future, as it has in the past, prevent excesses which are fatal to the soldier, soul and body. At present, every effort toward total abstinence at military posts merely opposes theory to facts and sentiment to statistics, and compels recourse to saloons of the lowest character, whose proprietors care nothing for the efficiency of the army or the ruin of a good soldier.

"(3) Every precaution should be observed to conduct post exchanges and the sale of light wine and beer along the lines recommended by Munson in his "Theory and Practise of Military Hygiene," pp. 820-822. and your committee begs to emphasize the fact that the bar features should be entirely abolished, and that the exchange should, in fact, be a soldiers' club, with ample facilities for reading rooms, legitimate amusements and athletic sports, where the soldier as a self-respecting individual may satisfy in an orderly manner his craving for diversion from the routine duties of a military life, without undue prominence of the refreshment feature.

"(4) The sale of soft drinks, warm lunches, coffee. tea, cocoa, bouillon, and soups should be encouraged as substitutes for alcoholic beverages, and medical and line officers should be directed to educate by precept and example the rank and file of the army; that for persons in health alcohol in any form presents no advantages not found in other foodstuffs or stimulants and which are moreover free from dangers attending its use. In this connection it should be remembered that good food, well prepared, and properly cooked and served, is one of the most effective prophylactic measures against the "drink habit" in civil as well as military life, and no effort should be spared to bring the culinary department in the army to the highest state of perfection.

"(5) Medical officers should point out the grave and far-reaching consequences of the effect of venereal diseases, so intimately connected with the drink habit, and make a strong plea in favor of continence. This may be done by letting these young men know that while the sexual passion is very strong, it can be accelerated or delayed, excited or lowered by the influence of the will. The soldier can be assured that by the cultivation of pure thoughts, removal of temptation, by normal mental, and especially vigorous physical, exercise, continence is not only possible, but easy.

"(6) Strong efforts should be made to improve the social conditions of the soldiers. There are times and occasion when the friendly advice of a company commander or attending surgeon, a personal interest in the physical and moral welfare of the young soldier, will prove of greater benefit than the cold verdict of a summary court martial. Such personal efforts on the part of the officers, dictated by the spirit of a universal brotherhood of man, appears to us perfectly compatible with proper military discipline. It is also believed that the habit of making savings deposits with the army paymasters may be greatly stimulated by personal efforts."

Health Report.—The following cases of smallpox, yellow fever, chorera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended January 2, 1904:

THE SERUM TREATMENT OF TYPHOID FEVER.*

BY MAX EINHORN, M.D.

PROFESSOR AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, NEW YORK.

[From the Beth Israel Hospital, New York.]

TYPHOID fever is one of the most serious and protracted of all acute infectious diseases. It is present everywhere and demands many victims annually.

The methods of treatment now in vogue had for their object the strengthening and sparing of the organism, in order to allow it to fight out its battle with the immigrated Eberth bacilli. We were, however, unable to support it directly in this combat. We could only pave the way for nature, but not enter upon it ourselves.

Since von Behring showed that diphtheria could be cured by a specific serum, a similar method of treatment has been looked for in typhoid fever.

Chantemesse[1] was probably the first to attack this problem successfully. His first experiments were undertaken in the year 1892, but were not crowned by practical results. It was only in 1899 that he succeeded in obtaining a serum, showing antitoxic and bactericidal properties for typhoid fever. At the close of his work Chantemesse says: "Having gained this experience, I have been able to inject a typhoid-fever patient with an antitoxic serum. The value of this new line of treatment cannot be judged except by the study of large statistics and numerous observations. I can, however, say that the serum acts in typhoid fever after the manner of an antitoxin, diminishing and suppressing nervous phenomena, lowering the temperature and effecting a cure."

Chantemesse[2] then treated one hundred cases of typhoid fever with this serum and published the results in 1901. According to him, the serum seems to exert a specific action; the duration of the disease is shortened and the mortality diminished. Chantemesse had a mortality of 6 per cent. with his method, whereas in other Paris hospitals it amounted to 10–20 per cent. Chantemesse advises the early use of injections even in cases in which the diagnosis of typhoid fever is not yet quite certain. The results seem to be better the earlier the treatment is begun. Danger from the serum treatment does not exist. Chantemesse compares the treatment of typhoid fever with that of diphtheria and says: "As in diphtheria, the serumtherapy of typhoid fever should be begun early. But the resemblance stops here. In diphtheria the serum suppresses or diminishes the intoxication and causes an expulsion of the microbes from the throat, whereas in typhoid fever the germs infesting the internal organs cannot disappear until surrounded and digested by the phagocytes. We can understand that these microbes, through the action of the serum, may be destroyed more or less quickly according to the vitality of the patient, and that those of the microbes that have escaped the action of the phagocytes may multiply and cause a relapse, which hardly ever occurs in diphtheria."

Bokenham,[3] Walker,[4] and Ewing[5] have worked in producing an antityphoid serum, but do not report any clinical results from it.

Jez[6] made an organic extract from the spleen, marrow, brain, spinal cord, and thymus of rabbits, which he had immunized against typhoid fever and treated typhoid patients with it. He gives it per os and in tablespoon doses and arrives at the following conclusions:

1. The Jez antityphoid extract is of specific therapeutic value against typhoid fever only.

2. It is a harmless preparation, which can be given even in large doses, without any untoward effects.

3. It is an aid in differential diagnosis.

4. If given uninterruptedly in typhoid fever it decreases the temperature and strengthens the pulse.

5. It shortens the duration of typhoid fever and diminishes or neutralizes completely the effect of the toxins of typhoid fever.

6. Taken per os it naturally cannot cause any such complications as sometimes result from subcutaneous injections.

Eichhorst[7] has treated two patients with a serum made in Berne without any appreciable results, but had excellent success in twelve patients treated with Jez extract.

Du Mesnil[8] later on treated a larger number of cases of typhoid fever with a serum also made by the Berne Board of Health (Drs. Tavel and Jez) and had good results.

Whereas the authors just mentioned ascribe to

TABLE OF CASES OF TYPHOID FEVER TREATED WITH ANTITYPHOID SERUM.

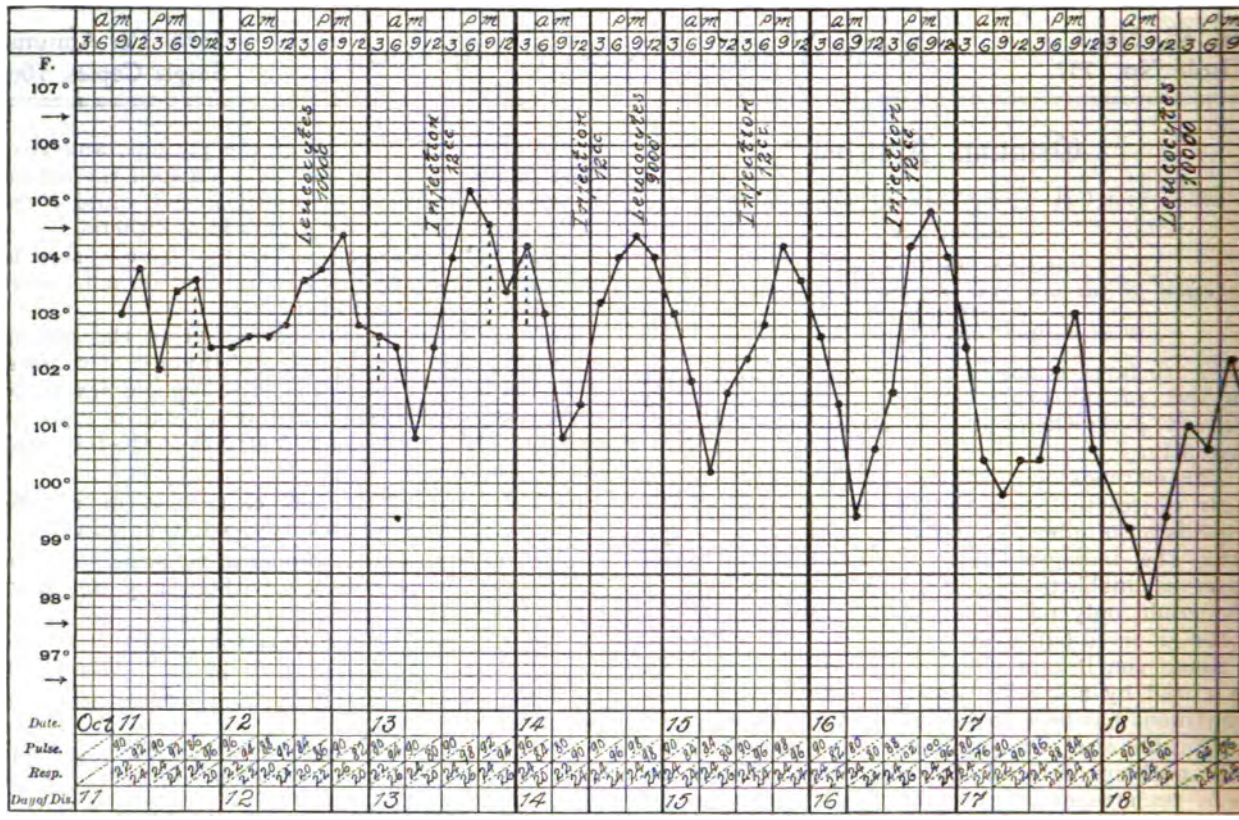
Name	Age	Widal	Day of disease on which injections were begun	Complications	EFFECT: On temperature. (How many degrees more the fever remitted than previously)	EFFECT: On general condition	Day of normal temperature
J. E.	16	+	10	...	1½°	Improved. Headache disappeared.	22
A. B.	16	—	16	...	1° Marked remission after second injection	Apathy disappeared	21
M. W. Severe case	12	+	12	Otitis media	1½° Temp. rising again	Improved	31
A. Br. Relapse	16	+	9	...	2° Marked remissions	Good	21
A. G.	36	—	15	...	1° After 2 injections	Headache and apathy disappeared	20
N. C.	19	—	13	...	1°	Mental condition much brighter	23
R. S.	13	+	15	...	½°	Good	21
A. S.	10	+	14	Double Pneumonia	No constant remission	Mental condition much brighter	38
Fr. G.	47	+	12	...	1° Relapse	At first good, later had no effect	60
Tillie S.	17	+	13	Double Pneumonia	1½°	Sensorium clearer; general condition better	33

*Read before the German Medical Society of New York, November 2, 1903.

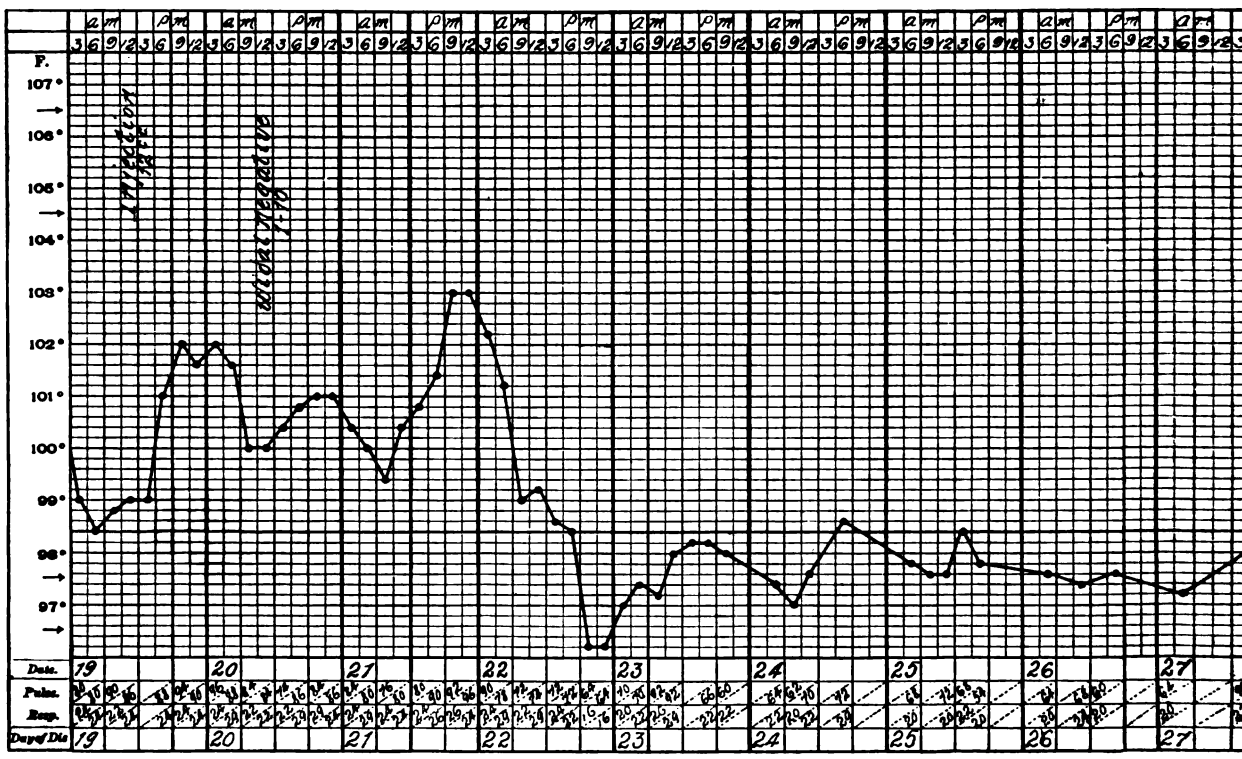
the new agent a specific action against typhoid fever, Widal[1] seems to be somewhat skeptical. Widal closes his remarks on serotherapy as follows:

"(1) Except for the diphtheria antitoxin, no serum seems to have given the results which laboratory experience would warrant us to expect in man. (2) It seems that all the so-called antitoxic sera act not upon the microbes nor the toxin, but upon the cells of the organism, which they aid in their combat with the microbes. (3) Therefore the ser of immunized animals do not at present seem t have any certain specific action, but only a gener tonic effect."

Under these circumstances, and considering th great importance of this subject for practica medicine, I have thought it of interest to give my own experience with serotherapy in typhoid fever This relates only to a limited number of cases, ye they seem to me sufficient to base a judgment upon

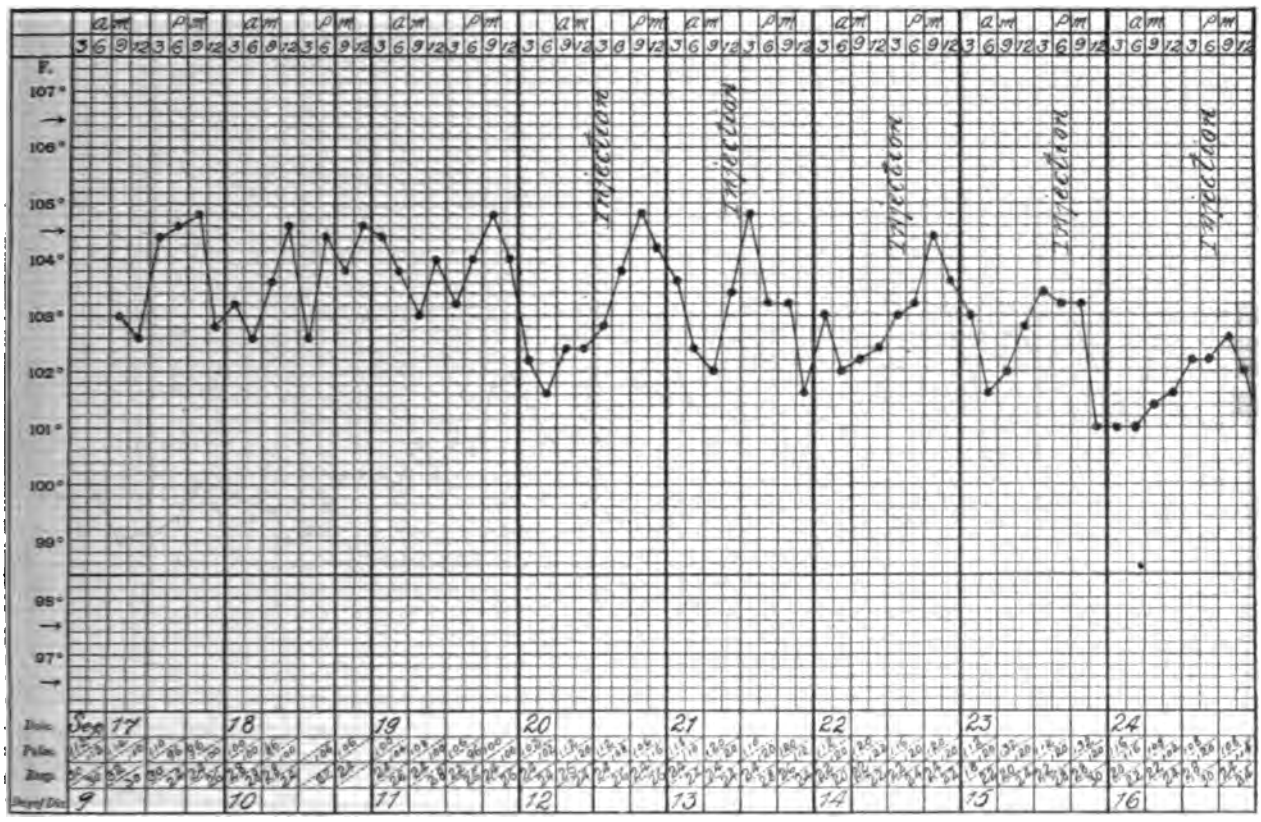


Case I (First part).

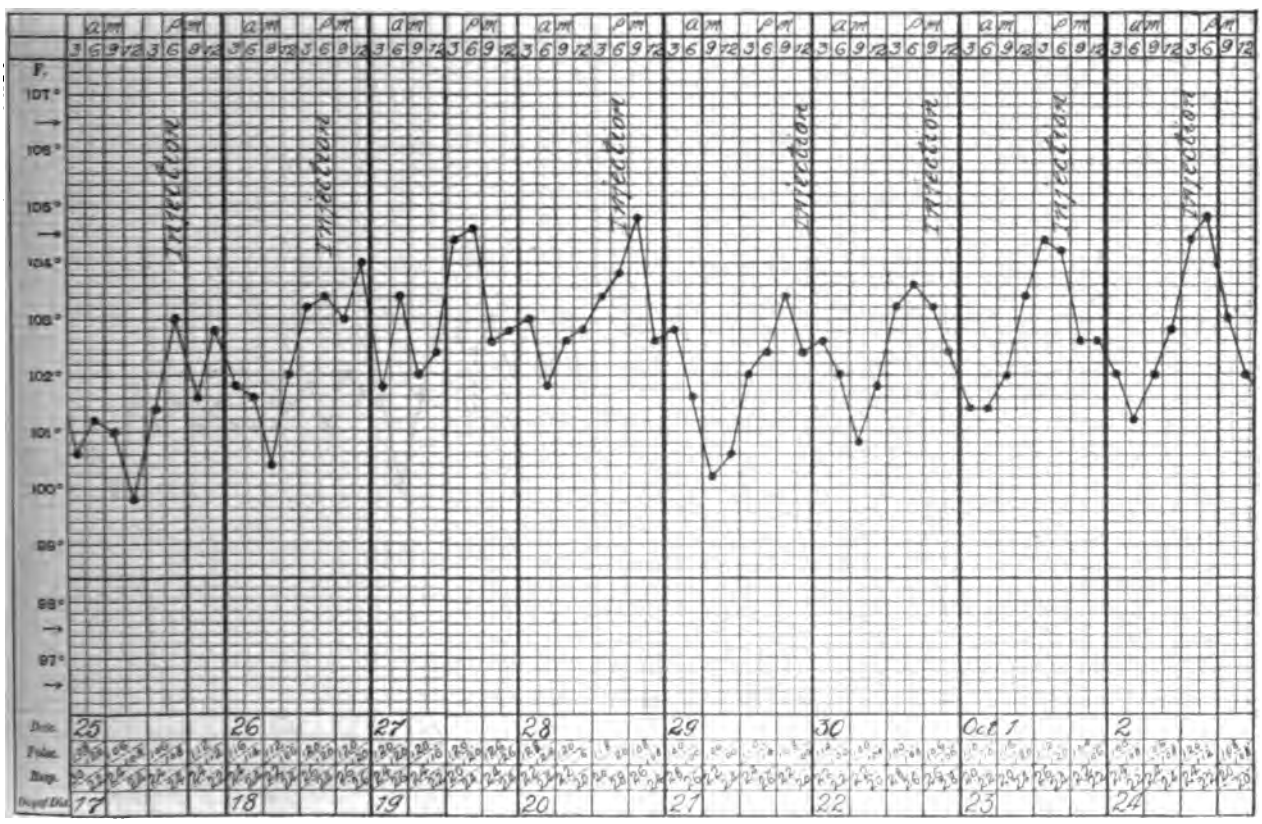


Case I (Second part).

I employed the anti-typhoid serum of Jez and Tavel of the Berne Board of Health. Expecting more striking results from subcutaneous injections of the serum than from giving it by mouth, I chose the first method for its routine employment, although in a few cases I also tried it per os. I used the serum, however, in smaller doses than advocated by Jez, on account of the comparatively small quantity of serum I had at my disposal. As soon as the diagnosis of typhoid fever was made (we usually waited until Widal reaction was positive), 6 to 12 c.c. of serum were injected daily until the temperature remained under 100° F.



Case II (First part).

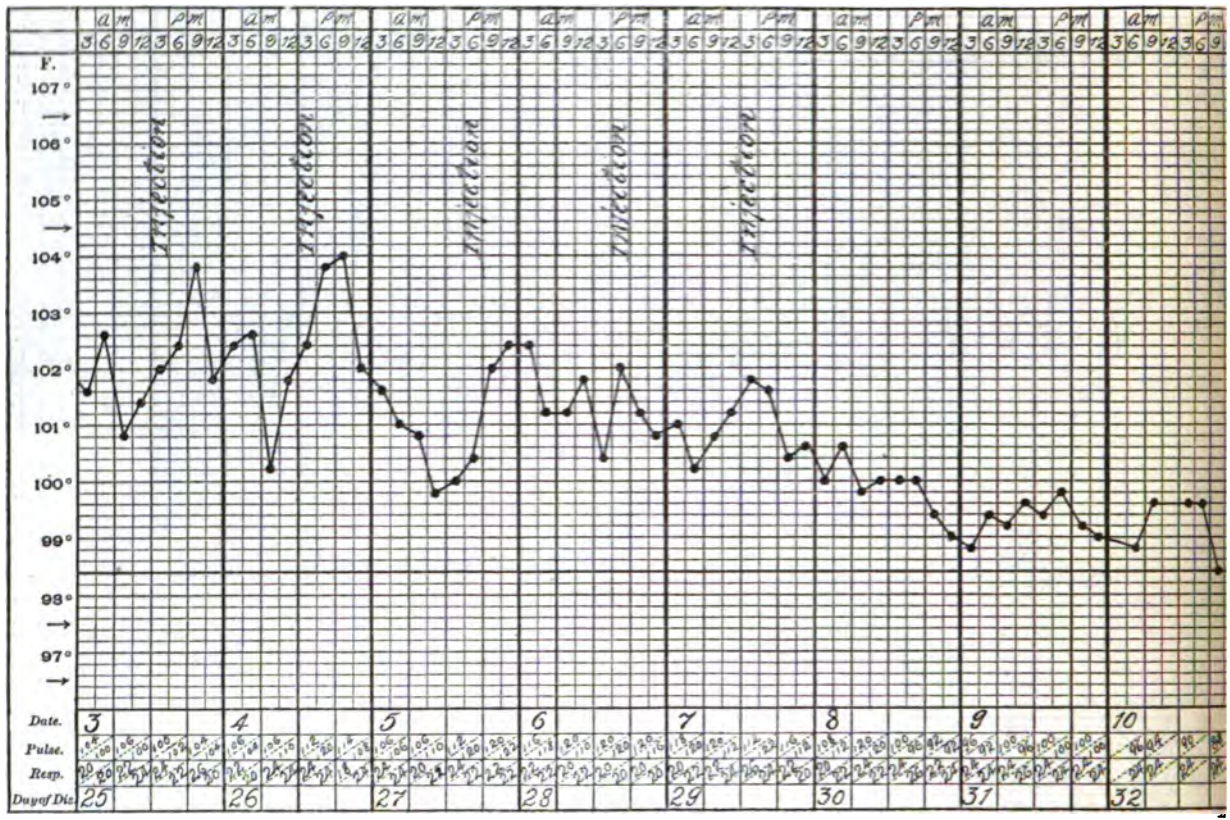


Case II (Second part).

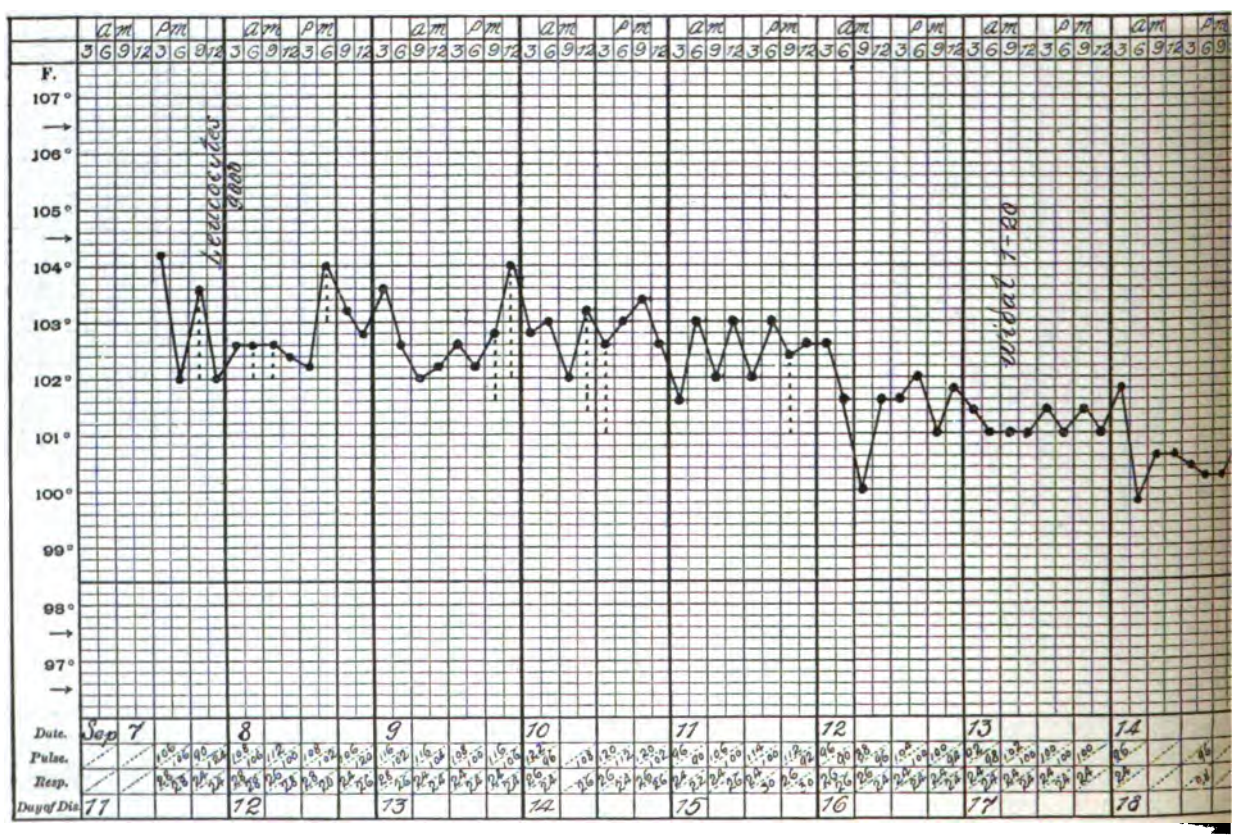
I chose for this treatment all medium, grave, and severe cases of typhoid fever which were observed in the hospital. Light cases of typhoid fever

were not subjected to the serum treatment. The number of patients treated with the serum was ten. In all the diagnosis of typhoid fever was certain. Seven gave a positive Widal reaction, whereas three showed no agglutination, but gave, otherwise, all positive signs of typhoid fever (enlargement of spleen, roseola, etc.). I may be permitted to put all cases treated with the serum into a table (page 81) and to give three histories with temperatur curves in a more detailed manner.

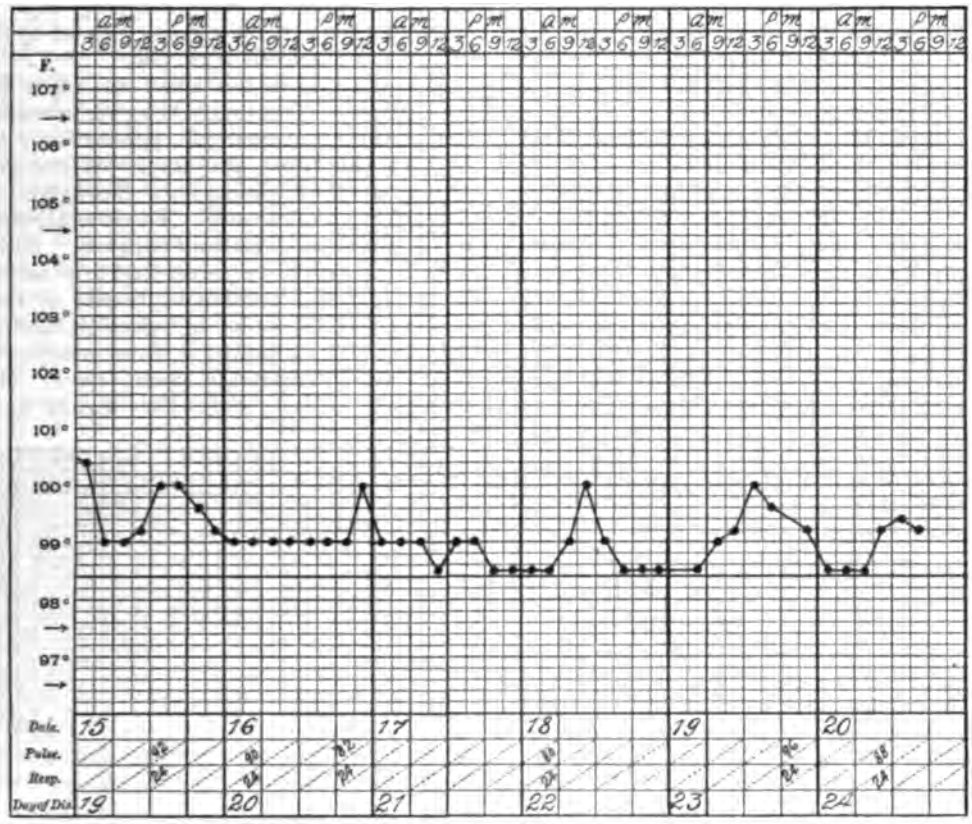
CASE I.—Nathan C., nineteen years old, admitte October 11, complains of chilliness, fever an weakness, headache and diarrhœa. Tongue mois and coated. Lungs negative, heart action vigorous sounds not quite clear. Liver normal. Spleen can not be palpated. Upper dulness at eighth rib



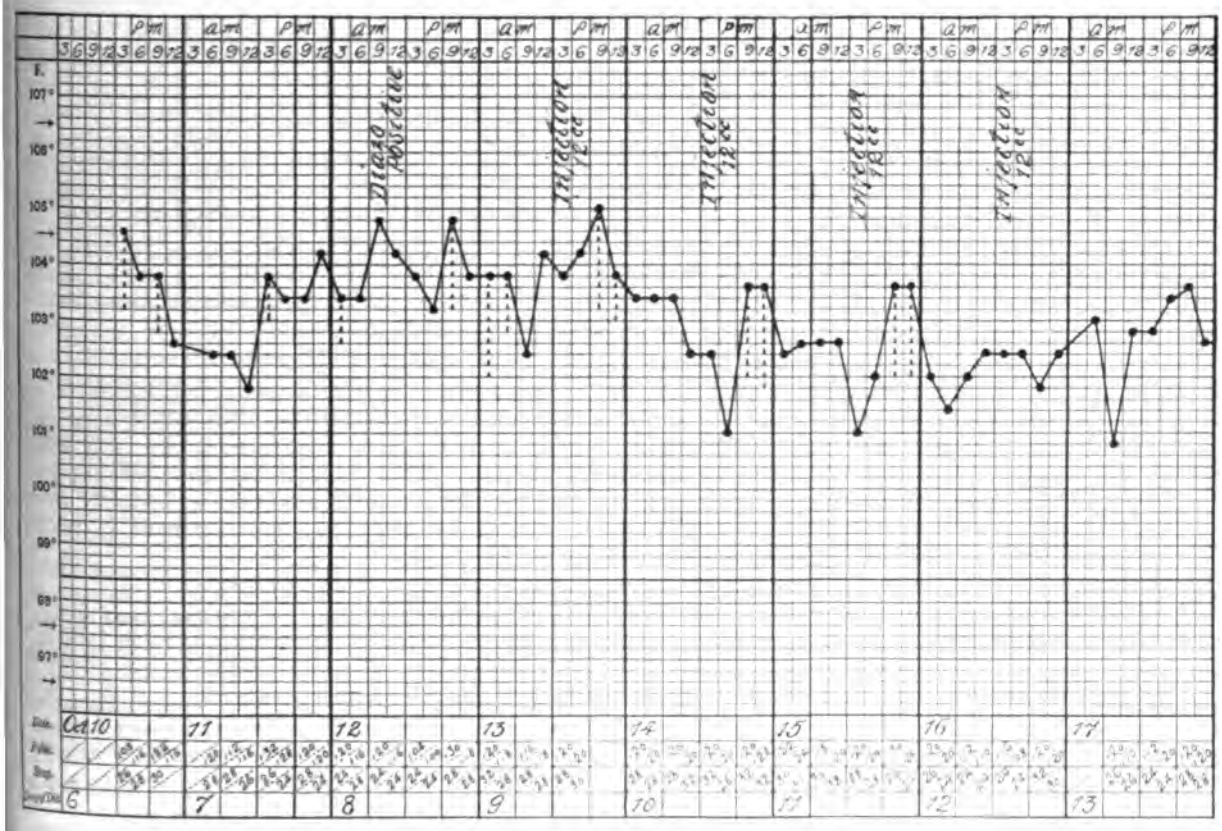
CASE II (Third part).



CASE III. First Period (First part).



Case III. First Period (Second part).



Case III. Relapse (First part).

serum treatment and a marked crisis on the twenty-first day of the disease, with subnormal temperature, lasting a few days.

Case II.—Meyer W., twelve years old, admitted September 17, has been complaining for the last eight days of headache, fever, and diarrhœa.

Status præsens: Apathetic. Purulent discharge from both ears. Heart and lungs negative. Spleen can be palpated. Roseola on abdomen and chest. Widal positive, 1–20. Red blood cells, 5,000,000. Leucocytes, 10,000. Hæmoglobin, 85 per cent.

Abdomen soft, not tender. Suspicious red spots over abdomen and chest. Leucocytes, 10,000. Red cells, 4,000,000. The temperature curve showed very steep remissions immediately after beginning

September 20. Condition unchanged, injection of serum.

September 25. Spleen hardly to be felt, roseola fading.

September 27. Spleen again palpable, fever higher.

October 1. Roseola reappears.

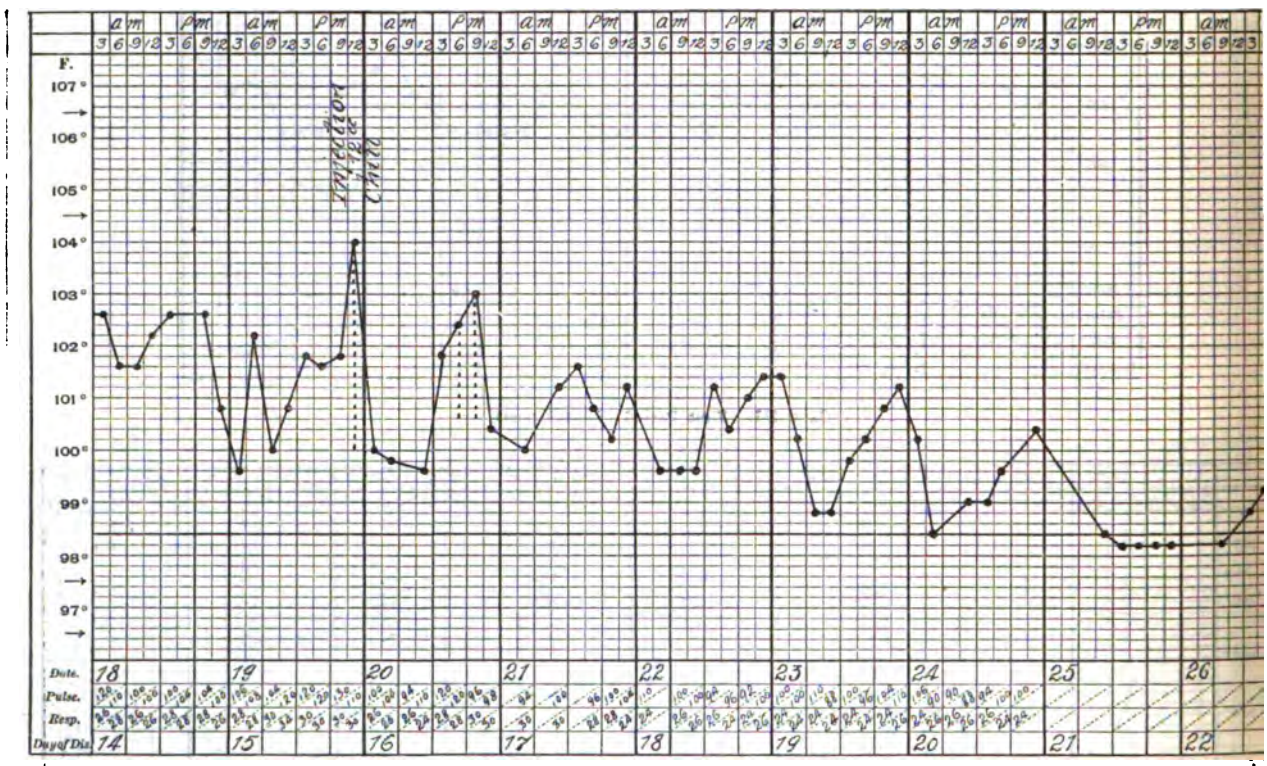
October 6. Left mastoid tender on pressure, roseola less.

October 9. Temperature normal.

CASE III.—Anna B. had typhoid fever twice this fall in the Beth Israel Hospital.

During her first illness serum was not used; during her second period of illness it was applied. The temperature curves of the first and second typhoid period in the same patient can well be compared, and thus allow us to recognize more easily the influence of the serum. We will therefore report this case in detail:

Anna B., sixteen years old, admitted September has been complaining for ten days of chilliness,



CASE III. Relapse (Second part).

fever, weakness, headache, slight cough, lack of appetite, and constipation.

Status præsens Spleen one and one-half inches below margin of ribs, roseola present, no diazo-reaction. Widal positive, 1–20.

September 20, dismissed. Returned on October 10, with 104.5° fever. Diffuse erythema of skin, large spleen, diazo-reaction present. Widal positive, 1–20; leucocytes, 7000.

October 26, dismissed.

In perusing this table and the histories we may draw the following conclusions with regard to the serum treatment of typhoid fever:

1. In most cases the disease does not seem to have been materially shortened.

2. Either on the day after the first or on that after the second injection a marked reduction of fever usually occurs; this is about 1 to 2 degrees lower than previous remissions and lasts longer. The general condition, especially the sensory and nervous symptoms, are much improved, so that some grave complications, such as sleeplessness, headache, restlessness, delirium, disappear nearly entirely.

As may be seen from the table the serum treatment of our cases was begun rather late, usually from the ninth to the fifteenth day. We may expect the results to be still better, if these injections can be practised still earlier. Chantemesse is certainly right in recommending injections, even in cases that are only suspicious of typhoid fever before the diagnosis is certain.

My material is too small to allow far-reaching conclusions. This much, however, we can assert, that the serum treatment of typhoid fever temporarily reduces the fever and improves the general condition, so that patients go through a more rapid and safer convalescence. The injections do not seem to be connected with any dangers. With the many injections given we never had any serious trouble; in two cases a passing erythema of the skin was observed at the point of injection, and in one case chills used to follow for from one-quarter to one half hour. Abscesses were never observed. We therefore believe that the serum treatment of typhoid fever is now already of decided value. There is no doubt that we shall soon have more potent sera, with which we may obtain more favor- able results. At all events the treatment originated by Chantemesse certainly means a lasting progress in the treatment of typhoid fever.

THE RÖNTGEN OR TRI-ULTRA-VIOLET RAYS, THEIR NATURE, APPLICATIONS, AND DERMATOLOGICAL EFFECTS.

By FRANCIS LE ROY SATTERLEE, Jr., A.M.,

DIRECTOR OF THE PHYSICAL AND X-RAY LABORATORIES, NEW YORK COLLEGE OF DENTISTRY.

In the latter part of the year 1895, Prof. Wilhelm Konrad Röntgen, while experimenting with a Hittorf tube of high vacuum covered with black cardboard, noticed that a screen "washed" with barium-platino-cyanide crystals gave forth a fluorescence in a darkened room. This accidentally discovered phenomenon was the nativity of what is now known as the ultra-ultra-ultra-violet or Röntgen ray, but which was then called, from the modesty of its discoverer, the "*x*" or unknown ray.

Before proceeding to narrate the course of investigations that followed this new development in the realm of science, it would be well, in order to have a clear understanding of the subject, to review some of the earlier researches with tubes of varying degrees of exhaustion made by Faraday, Geissler, Crookes, Goldstein, Hittorf, and Lenard.

Michael Faraday was the pioneer in these investigations; as early as 1838 he conducted a series of experiments with an electrical discharge through rarified gases, and invented the terms anode and cathode for positive and negative electrodes. He was followed some time later by Gassiott whose ideas were afterward carried out by Geissler of Bonn, the first to construct the tubes that now bear his name.

Up to this point the investigations proved but of little importance beyond the fact that any rarified gas gave forth a peculiar light or phosphorescence when subjected to an electrical discharge. Air produced a pale violet glow, hydrogen a red, and carbon dioxide a steel blue shimmer.

It remained for Professor Hittorf, the celebrated electrician of Munster, to experiment with a Geissler tube of higher degree of vacuum. He noticed an increasing resistance to the coefficient of rarification. He also observed that the glow proceeded in straight lines from the negative electrode, casting a shadow of an interposed object upon the opposite wall of the tube and furthermore disclosed the fact that these rays were capable of deflection by a magnet.

Mr. Crookes, afterward Sir William, was the next investigator to enter the field of research, and in 1878 made some interesting announcements that did a great deal toward popularizing the subject. He experimented with the rectilinear rays of the Hittorf tube, and devised the theory that the rectilinear path was caused by the current attaching itself to freely moving molecules of gas as it left the cathode and proceeded in parallel lines with great velocity and bombarded the opposite side of the tube, or other intervening object, with terrific impact. He also succeeded in focusing these rays of rapidly moving molecules by curving the cathode, thus giving it the form of a concave mirror, and thereby projecting the rays to a common point, instead of in parallel lines. Objects placed at the focus of these rays were heated to even whiteness and this was supposed by Dr. Crookes to be caused by the "bombardment" from the enormous quantity of projected molecules.

Simultaneously with this announcement by Sir William Crookes, M. Goldstein came forward with the theory that the phenomenon was caused by a transmission of energy and not by the bombarding with actual particles, but he could not give any definite explanation of his "transmitted energy."

Professor Weidemann of Leipsic, in 1883, was the first to ascribe to the "cathode rays" the possibility that they were in reality light waves of extremely short wave length at the remote end of the spectrum, far beyond the violet light. Paul Lenard, a pupil of the famous Professor Hertz, also believed in this hypothesis, and in a series of experiments conducted at Bonn, proved conclusively that there was not only evidence of cathode rays outside the generating Hittorf's or Crookes' tube, but that furthermore, the rays even penetrated a thin sheet of aluminum foil, a fact that none of the investigators previous to this had so much as dreamed of.

Prof. J. J. Thompson of the Cavendish Laboratory, Cambridge, by an ingenious method afterward succeeded in actually measuring the velocity of these "cathode rays," as they began to be termed, and this velocity he approximated to be 200 kilometers, or about 124 miles a second. It might be well to mention in reference to Professor Thompson, that he advocated still another hypothesis in regard to the nature of the cathode rays similar to, yet differing from, that of Crookes, namely, that the molecule of electrically charged gas, or atmosphere, splits up into two or more "ions." This term, meaning traveler, was so named by Faraday, who has added largely to the nomenclature of electrical science and which has long been used in connection with such electrically charged portions of matter as were known to exist in the passage of a current of electricity through a liquid.

After a long period of dormancy following the assertions of Paul Lenard, the world was once more aroused by the proclamation of Prof. Wilhelm Konrad Röntgen in the year 1895, that he had discovered an entirely new ray differing from any of the cathode rays that had formerly existed.

The strange fluorescence of platino-barium-cyanide crystals, on exposure to what Professor Röntgen had considered to be cathode rays, led this scientist to continue his investigations along new lines and to experiment more specifically with the fluorescence with most surprising developments. He found that his fluorescence still continued even when a book of 1000 pages was interposed between the screen and the source. He also found that this fluorescence had an actve influence on a photographic plate. Professor Röntgen next proceeded to experiment with objects of varying transparencies which led to the discovery that a human hand interposed between the generating tube and a photographic plate disclosed on development all the bones of the hand, since the ray had penetrated the flesh more easily than the denser bone.

This revelation was received by the scientific world with amazement, and the enthusiasm of the medical profession was henceforth enlisted.

In Professor Röntgen's original communication to the Wurzburg Physico-Medical Society, dated December, 1895, he describes some of his experiments and the conclusions that he deduced from them. Among other things, he showed that the rays were not polarizable, nor could they be reflected, consequently he found that they could not be concentrated by lenses. He also found that the transparencies of different bodies under the influence of the *x*-ray depended entirely upon their density.

This law he based on the following experiments (to quote from his communication):

"Sheets of platinum, zinc and aluminum were rolled until they appeared to be of almost equal transparency" (by the photographic plate). "The following table gives the thicknesses in millimeters

the thicknesses relative to the platinum sheet, and the density:

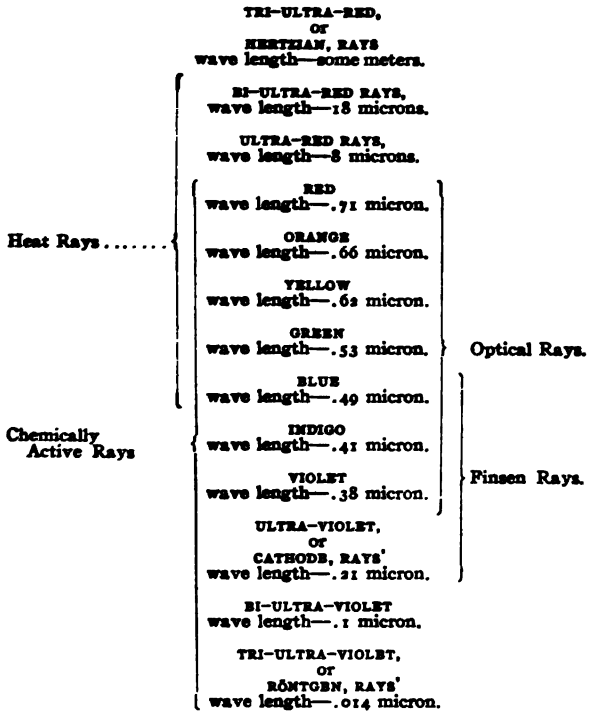
Thickness	Relative Thickness	Density
Pt. 0.018	1.	21.5
Pb. 0.05	3.	11.3
Zn. 0.10	6.	7.1
Al. 3.5	200.	2.6

"It is to be observed in connection with these figures that although the product of the thickness into the density may be the same, it does not in any way follow that the transparency of the different metals are the same. The transparency increases at a greater rate than this product decreases."

Professor Röntgen concluded his paper with the hypothesis that the *x*-rays were perhaps due to longitudinal vibrations of the ether.

Since that date there has been a large number of investigators in the field, many of whom have advanced some hypothesis or another concerning the exact nature of the Röntgen rays, but the old theory that Professor Weidemann brought forward in 1883, in reference to the cathode rays, was applied to the Röntgen radiation and is now the only explanation that has survived the critics of the scientific world.

In the accompanying diagram I have prepared a practical presentation of the Weidemann theory, showing the relative arrangement.



Note—One micron=one-millionth of a meter.

Starting at the very lower end of the spectrum, we have the Röntgen rays or, as I have called them, the tri-ultra-violet rays with an estimated wave length of .014 micron. The next step I have called the bi-ultra-violet or Bequerel rays, consisting of the rays given off by such radioactive substances as radium uranium salts, polonium, and the like, with a wave length of .1 micron. Next, we have the ultra-violet radiation known as the cathode rays of Weidemann. Crookes, and Lenard, of about .21 micron in length. Above this come the violet, indigo, blue, green, yellow, orange, and red rays with their estimated respective wave lengths, and still beyond these are ultra red and, as I choose to call them, the bi-ultra and tri-ultra-red rays. Between the last named and the bi-ultra-red division of the spectrum there exists a gap which is accounted for by the difference in the wave length of the two rays. What occupies this gap we have been so far unable to discover. The tri-ultra-red rays consist of the electromagnetic or Hertzian rays, now utilized for wireless telegraphy.

I have been for some time past investigating the relations of these Hertzian rays with those of the ultra and bi-ultra-red rays with a view to establishing a classification of the rays that occupy the gap. It is my earnest conviction at the present time that these unknown rays are of an electrical nature. I believe that in this space we have the gradual descent from the known electromagnetic rays of tremendous wave length through the different shades of magnetic and electrical phenomena of shorter wave length, down to the thermoelectrical rays and the known thermal rays that compose the ultra and bi-ultra-red rays of about 1 to 18 microns in length. I am, I believe, the first to promulgate this hypothesis, and I hope that in the near future I may so complete my investigations that I can then offer to the scientific world the proof that is now lacking to my theory.

Let us now consider the methods of producing the Röntgen rays. This can be done in three ways—by means of the static machine, the Tesla coil, or by the induction coil. The first two are now seldom used, since with the induction coil of the present time we have the ideal method.

When Professor Röntgen's discovery was first made known, the physicians and other scientists resorted to the static machine as the generating source of electricty to a great extent, but this apparatus gradually gave way to the induction coil, since with the latter a more powerful and energetic ray was produced, consequently diminishing the length of exposure to a minimum.

The Tesla transformer, or coil, was also used by some, but although very powerful rays were generated in the vacuum tube, the potential of the current was very high and frequently resulted in the puncture of the tube.

An induction coil has been recently constructed especially for Röntgen-ray work, which has proved to be far superior to any that have hitherto been used. This instrument when used in connection with a special form of interrupter will generate rays that have never been equaled either in intensity or quantity. It will light up any tube that is made. These coils are known as the Wappler coils.

The interrupter must be of the electrolytic order and capable of making 250 breaks a second.

To complete this apparatus we should have a suitable rheostat, a commutator, and a supply of vacuum tubes. The latter requisite is really the most important in *x*-ray work, since even with the best coil and outfit poor results will be obtained if the operator has not a good tube.

There are many kinds of tubes, and it might be well to give a little space to their construction and theory.

Röntgen ray tubes may be said to be divided into three classes, namely, the non-regulating vacuum tube, the adjustable vacuum tube, and the self-regulating tube. A simple form of the first class consists of a glass tube with two elongations into which are introduced two electrodes. The negative electrode has an aluminum concave disk mounted at the end, while at the positive electrode we have a flat disk of platinum placed at an angle of about 45 degrees. The tube is exhausted to about a millionth of an atmosphere. The induced current enters the tube through the cathode by means of a wire, and cathode rays are formed. These rays fall upon the anode disk, and some of them are transformed into Röntgen rays and are diffused in all directions on the side of the anode facing the cathode. The electrical current passes

through the anode and thence through the wire back to the induction coil. This form of tube is called a simple-focus tube, from the fact that the cathode is concave and tends to focus the cathodic stream upon the anode, which is placed at an angle, thus acting as a reflector to the rays.

Tubes of the second class consist of adjustable-focus tubes of the anticathode type. In this tube we have a primary and secondary anode. The former is called the anticathode and is identical to the anode of class one, while the real anode acts as an auxiliary electrode to catch any of the overflow cathodic stream that might pass the anticathode and to convey off the surplus electricity. The two anodes are connected by a wire. A regenerative attachment to renew the gas supply to the tube when the vacuum has been raised by continued use. consists of a platinum wire fused into the neck and, like most of the metals of that group, has the property of giving up its occluded hydrogen, upon the application of heat. A protecting glass cover or cap fits over this attachment. It follows therefore that when the cap is removed and the wire heated in a spirit or Bunsen flame to a cherry redness, the occluded gas will be given off in the tube, thus lowering the high vacuum that exists.

The third class is composed of tubes of the self-regulating vacuum type. A small bulb containing a gas is directly connected with the main tube and is surrounded by an auxiliary tube which is of low vacuum. The anode of the small tube is opposite the discharge bulb, while the cathode is connected with the anode of the main tube. An adjustable rod is connected with the minor anode and acts as a spark-gap regulator. The main tube is of high vacuum, and when a current is passed through it, it will take the course of least resistance through the low-vacuum auxiliary tube. This will send cathode rays toward the protective platinum tip of the discharge bulb, and at the same time generate heat which will liberate some of the confined gas into the main tube till the vacuum is so lowered that the current will easily pass through it. When the tube again reaches the stage of very high vacuum through continued usage, the same operation is automatically repeated.

It would seem from this description that the last class of tube is superior to all others; but there is a drawback from using this type of tube, and that is the tendency it has to liberate too much gas and reduce the vacuum in the main bulb unduly.

On the whole, I have found the second class of tube the most satisfactory in the long run. This tube is made in several forms in which the anode has some cooling attachment. A great disadvantage with most Röntgen-ray tubes is that the platinum anode sometimes becomes overheated and even melts. To remedy this difficulty, tubes have been constructed with platinum anodes mounted on cast-iron bases that extend back into the neck of the tube. With this contrivance the danger of overheating is minimized, since the iron core conducts the heat away from the platinum disk. Another form is where the anode is mounted on the end of a glass tube of about one-half to one inch in diameter fused into the bulb. This tubular anode contains water, which acts as a cooling agent to the platinum. A wire running through the water tube connects the disk with the electrode terminal.

Of all the tubes that are made, I think that the Mueller tube, of Hamburg, is perhaps the most reliable and satisfactory. The gold medal was awarded them by the Röntgen Society.

Before leaving the subject of *x*-ray tubes I wish to call the reader's attention to a comparative table of tubes of high and low vacuum which I have prepared:

High-Vacuum Tubes.	*Low-Vacuum Tubes.*
One millionth per cent. vacuum.	One thousandth per cent. vacuum.
Hard tubes.	Soft tubes.
Small volume of rays.	Large volume of rays.
More penetrating rays.	Less penetrating rays.
Giving off more electricity.	Giving off less electricity.
Less contrast in radiograph.	More contrast in radiograph.
Bones white with fluoroscope.	Bones black with fluoroscope.
Less danger of dermatitis.	More danger of dermatitis.

The original fluoroscopic screen used by Professor Röntgen was composed of platino-barium-cyanide crystals.

This was superseded very shortly by the discovery of Mr. Edison that a screen coated with tungstate of calcium crystals exceeded in fluorescent qualities the platino-barium cyanide of Dr. Röntgen. Since then many experiments have been made with fluoroscopic screens, with the result that Mr. C. A. F. Kahlbaum of Berlin has placed upon the market a screen which has proved far superior to any hitherto manufactured. He has, like Professor Röntgen, made use of platino-barium-cyanide crystals, but they are of a better grade and are somewhat larger. His discovery lies entirely in the method of making the crystals. A good tube, a Kahlbaum screen, and a Wappler coil, would make as perfect a Röntgen-ray outfit as any operator could desire.

To operate the Röntgen ray successfully, the operator must have, besides the above-mentioned apparatus, a suitable laboratory, a photographic dark-room and its accessories, and a lead-lined chest for storing plates and films. The last-named may be omitted if the plates are kept sufficiently far away from the laboratory, as the rays have a very great penetrating power.

I have spoiled a supply of plates that were inclosed in an iron chest, the walls of which were a quarter of an inch in thickness, and which was over thirty feet from the operating tube.

The laboratory should be a large room that can be made absolutely dark. It should have dark-colored ceiling, walls and floor. A rack should be made on one of the walls to hold six or eight tubes. There should be a firm table with a drawer and casters upon which to place the coil, rheostat, and commutator; a shelf underneath the table should hold the interrupter; an adjustable tube holder, that stands about three or four feet from the floor, and a suitable operating table with chairs, and an extra table or desk should be added to the laboratory and to complete the furnishings, a curtained-off corner should be available for a dressing room. If the operator is going to do dental work as well, a dentist's chair will be found very useful.

To operate: the coil, rheostat, commutator, and interrupter must be connected with the electric-lighting circuit (or storage batteries may be used) in series; next, the two terminals of the coil should be connected with the two electrodes of the tube by means of wire. I have found that the ordinary ten-ampere fuse wire is the best for the purpose. The current is then turned on with plenty of resistance in the rheostat. If there is a number of moving circles of green light in the tube, the polarity is inversed and the commutator must be shifted; if there is an even greenish-yellow light in the tube proceeding in a hemisphere from the anode disk, the polarity is correct. If the light is very weak and intermittent, there is too much resistance in the rheostat, but care must be taken not to throw out all the resistance till the tube has been used for some time, as there is a great danger of puncturing the glass wall of a new tube. The light in the room can now be extinguished, and after waiting a few minutes for the eyes to become accustomed to the darkness, the hand may be held in front of the tube

and the fluoroscope can then be used to examine the bones. If the shadow of the flesh appears very black and the bones hardly visible, the tube is either too low or there is too much resistance in the circuit. If on the contrary the flesh is hardly visible and the bones appear very white, the tube is too high, and must be lowered for radiographic work unless the operator wishes to take a picture of the pelvis, hip, or thorax. In a tube suitable for fluoroscopic examination or for general radiographic work, the bones of the hand should appear quite dark and well defined, while the outline of the flesh should be very distinct.

When the picture is to be taken the patient should remove all clothing from the part to be taken, and (if any part of the body but the hand or forearm) should lie upon the operating table.

This table consists of a stretcher made of canvas and mounted on four firm legs with casters. Over the canvas are three boards that slide along the frame work of the table. The patient lies upon the boards, with the part of the body to be radiographed resting lightly upon the canvas. A photographic plate, suitably wrapped first in black and then in yellow paper, is placed under the body with the sensitized side touching the body. The tube is then adjusted in the tube-holder so as to be directly over the part of the patient to be taken, the surface of the anode being parallel to the part to be radiographed. The current is then turned on and the lights extinguished. When turning off the current, care must be taken not to remove the plate for two or three minutes after the light in the tube has completely disappeared, or else a blurred picture will be the result, due to the residual rays left in the tube.

Before taking the picture, the part to be exposed should first be viewed with the aid of a fluoroscopic screen, if possible, in order to ascertain if the tube is in good condition and the picture shows sufficient contrast.

Very little can be said about the length of the exposure, since every tube and every coil has its own time standard, which the operator must ascertain by experiment.

The average time required with the improved apparatus now upon the market is only from two to six minutes for the pelvis or thorax, while radiographs of the hands, teeth, and forearms are made in a few seconds.

It has been proven by some operators that if a fluorescent screen be interposed between the plate and the body, the time of exposure can be materially lessened. This is true; but the resulting picture is very poor in detail and has a granular appearance that renders it useless for diagnostic purposes.

Soon after Professor Röntgen made his announcement in 1895, scientists all over the world took up the subject and started a campaign of investigation; and in the course of these experiments many persons were subjected to the direct exposure of these unknown rays. It soon began to be noticed that when a patient or subject had been under the influence of the *x*-rays for any length of time, an acute attack of skin inflammation or dermatitis was the result. This unlooked-for phenomenon was at first attributed to some other cause, till at length the increasing number of cases convinced physicians in general that it was the *x*-ray itself that was the seat of all the evil. Naturally, this was the theme for many a newspaper article, and in fact such a furor was set up that many operators ceased their experimenting entirely. This state of affairs lasted for some time, increasing at every new case that was recorded of "*x*-ray burns," and "Loss of hair and finger nails," and even "Gangrene resulting from *x*-ray burns." This new development did a great deal toward discouraging the use of the Röntgen rays as a special branch of surgery, and indeed came near inflicting upon the wonderful discovery its death blow. But such was the case, and if it were not for a few faithful followers, the Röntgen rays would have drifted into the sea of oblivion.

The cause for these burns was for a long time thought to be the electricity given off from the tube, and it was not till Dr. Robert Keinbock of Vienna began a series of investigations that the real source of the damage was discovered. He submitted a large number of people to tubes of very high vacuum. The exposures were from ten to fifteen minutes' duration. After eighty sittings few effects were noticed beyond a slight irritation of the epidermis, which healed simultaneously with cessation of the sittings. He then substituted low vacuum tubes for the high ones, and after comparatively few exposures the patients were all suffering from intense inflammation of the skin.

Dr. Keinbock then formed his conclusion that the electrical discharge was not active on the skin, but it was the action of the rays themselves that produced the dermatological effects. His theory was based on the fact that a low vacuum tube was far richer in Röntgen rays than the high ones, and that the hard tubes were capable of giving off more electricity than soft ones He further proved this hypothesis by submitting a rabbit to the rays of a low tube which was so arranged that the surface of the anode was perpendicular to the body of the animal. He found that dermatitis was set up on the skin of the rabbit, starting from the projection of the anodic surface and extending toward and beyond the projection of the cathode. This seemed a most conclusive proof, since the tube was equally charged with electricity on one side of the anode as the other, and the greatest intensity of the rays was in a direction perpendicular to the surface, and decreased as the cosine of the angle of obliquity in any direction. At this rate there would be practically no rays in a direction at right angles to the axis of generation or in the axis of the ordinates.

This theory is now looked upon as the correct solution of the mystery, although the exact dermatological transformation that goes on is still unproven. It is supposed to resemble a sunburn in its pathological effect.

A theory was brought forward sometime ago that minute particles of platinum were thrown off and imbedded in the skin, thus causing the irritation. This was absolutely disproved by Professor Gilchrist, who had a section of skin from a very bad case of dermatitis chemically analyzed, and it was found to contain not the faintest trace of platinum.

No means have so far been discovered to prevent the development of dermatitis, if the patient is exposed any length of time, or if the sittings are often repeated.

Since the advent of the new and approved Röntgen ray apparatus there is no necessity in exposing the patient to the rays more than a few minutes at any one time (unless the ray is being used as a therapeutic agent), and therefore it is only the carelessness of some inexperienced operator that will allow a patient to become burned.

The only precaution that an operator need take beyond not exposing a person to the ray for more than twenty minutes in the aggregate, unless a period of two or three months intervenes, is to cover all the portions of the body that are under

the influence of the rays and are not necessary for the operation, with heavy pieces of lead foil, thus cutting off all the rays from unnecessarily penetrating the rest of the body.

A case of dermatitis once developed, it is very hard to make it yield to any treatment, and it will require at least several months for the lesion to subside. However, in the course of experimenting, I have found that the prescription, an application of one part of carbolic acid in eight parts of rose-water ointment made to the inflamed parts on retiring, will tend greatly to reduce the irritation. This formula was the discovery of my father, Dr. F. LeRoy Satterlee of New York City, who has used it in his practice for many skin irritations for the last thirty years or more, with most satisfactory results.

It was at his suggestion that I applied it, with excellent results, to a case of dermatitis on my own hands, brought on by constantly being around the discharge tube and often interposing my hand between the tube and fluoroscope to judge the definition of the ray.

The Röntgen ray has many applications in science, and even in the arts we have some uses for its peculiar properties. It is unnecessary for me to dilate here upon its general applications, since they have been discussed in almost every magazine or journal all over the country. I will, however, bring up some of its special uses and recent applications.

There is an impression now among a great many scientists that the Röntgen ray is a positive agent for diagnosis. This idea is decidedly erroneous, since distortions so frequently occur in the radiographs. A proof of this is the fact that where formally radiographs were used quite often in the courts, they are now seldom admitted as evidence, for the reason that radiographs of a fracture, for instance, can be manufactured where the fracture never existed.

This does not, however, detract from the general usefulness of the rays as an important factor in surgical diagnosis, since by its use a physician or surgeon can operate with the greatest certainty in regard to the supposed abnormality or condition.

In dentistry the Röntgen rays have become a necessary adjunct. By their aid, non-erupted teeth may be at once located, deformed and abnormal roots can be followed in their sockets, diseases of the pulp canals examined, broken instruments, and foreign bodies and fillings can be outlined, as well as abscesses of the alveolar process and necrosed conditions of the maxillæ.

For purposes of instruction in some branches of science the rays present a practical and unique method, as, for instance in physiology, lantern slides can be made from actual radiographs of the stomach during the several stages of digestion, the subject first having taken subnitrate of bismuth (or some other harmless substance opaque to the Röntgen rays) mixed with the food. This will outline the organ and its contents, showing in a most beautiful and realistic manner the seven different phases of digestion.

In anatomy, radiographs of the bones and joints can be converted into lantern slides and present to the student far better and truer pictures than can be made from woodcuts or observations of an articulated skeleton. Also, Röntgen ray clinics can be made of practical value to the student.

As a therapeutic agent the Röntgen rays seem likely to become more serviceable to humanity than even its application in surgical and medical diagnosis.

The rays have been used with unquestionable success in treating some of the most formidable diseases that afflict the human race, among which can be numbered: Lupus vulgaris; lupus erythematosus; carcinoma, external, scirrhus and epithelioma; enlarged glands, scrofulous or otherwise; sycosis and favus; molluscum contagiosum; phthisis, pulmonary and laryngeal; rodent ulcer; hypertrichosis; pruritus; neuralgia; chronic eczema; acne; warts, etc.

In many cases it may be necessary to produce dermatitis in order to heal the more serious lesion, while in others, comparatively, a few treatments will suffice to bring about an effective improvement of condition.

A great deal has been said on the permanency of the cures achieved by the Röntgen rays, but there are many cases on record in which a chronic condition has been completely removed and no reappearance had developed in two or three years. Of course beyond that time we cannot tell what may happen, but it seems very probable that in the majority of cases the cure is permanent.

In Röntgen ray photography the resulting picture is called by a variety of names, as a radiograph, radiogram, skiagraph, skiagram, cathode photograph, shadowgraph, electrograph, skotograph, and Röntograph.

In a radiograph, unlike a photograph, no camera is used, but the plate, properly wrapped in light-proof paper, is exposed to the generating Röntgen ray tube with the object to be taken interposed between the two and touching the film side of the plate.

A radiograph differs from a photograph mainly in the fact that the former is a shadow of the object taken, whereas the latter is a reflected image. This difference serves in some ways to reverse the general ideas in photography governing the development of plates. A "plate," as it is called either in photography or radiography, consists of a piece of glass coated with a solution of gelatin and either silver chloride or silver bromide (usually the latter). A plate thus prepared is sensitive to all light, since the action of the actinic rays decomposes the silver bromide AgBr. into the sub-bromide of silver Ag_2Br. This chemical change does not visibly affect the plate, but when it is subjected to the action of a reducing agent, as a "developer," the sub-bromide of silver is again partially changed to metallic silver. Now the plate is immersed in a "fixing" bath, which finishes the reduction of sub-bromide to metallic silver and makes it permanent and dissolves off all of the silver bromide unaffected by the light. This constitutes the technique of photography. The same changes take place in radiography, except that the image is a protected portion of the plate and remains after exposure to silver bromide, while the part of the plate not occupied by the image is converted by the action of the Röntgen rays, as of ordinary light, into the sub-bromide of silver.

Thus we have a finished negative with a dark background, while in photography the background is generally light. The treatment of the radiographic negative is practically the same. A very slow developer—that is, a weak solution—is desirable, since there is but little detail to be had compared with the photographic negative and slow development is necessary to bring it all out. A plate may be "developed up" so that the image is apparently entirely obliterated and it will reappear with good intensity in the "fixing bath."

A developer that is recommended for *x*-ray plates is the "Ortol Normal." I have used it with very good success in my radiographic work, and have found that it brings out the detail well. I have found that a developer of hydochinon and

metol for contrasts used in conjunction with the above gives excellent results.

A practical scheme for numbering plates and films simultaneous to the taking of the radiograph, devised by Dr. F. VanWoert of Brooklyn, is to stamp the numbers in a thin strip of aluminum and then fill in the indentures with red lead. Those numbers are then cut from the strip in small squares and are laid inverted upon the envelope of the film or plate to be taken (on the sensitive side). A gummed label is then placed over the number to keep it in place. Now when the plate is exposed the image of the number appears on the negative, since the rays penetrate the aluminum more easily than the red lead.

There are many other suggestions that might be added to the radiographic notes, but they border on pure technique of an elementary nature which I have striven to eliminate from this dissertation.

It is now just seven years since the Röntgen ray was made known to the world, and in that time its development has gone on uninterruptedly, except for a short time when the public were up in arms at its dermatological "offences." But it was this very "offence" that gave to the scientific investigators the impetus necessary for the discovery that the rays were rich in curative as well as damaging effects. The outcome of which is that thousands of persons are now perfectly well and strong who prior to this time had been suffering from chronic disturbances. Who can tell what the future of such an all-powerful agent is to be? Was it not many years after the actual discovery of electricity that the benefits began to be felt? Is not electricity still in its infancy? If such is the case, what are we to think in regard to the development of the Röntgen ray?

The tri-ultra-violet rays of the future will undoubtedly disclose rare and unique wonders to the never tiring delvers in the vast field of science.

X-RAY DERMATITIS AS INFLUENCED BY IDIOSYNCRASY.

By A. D. ROCKWELL, M.D.,
NEW YORK.

While it is yet too early in the use of the *x*-ray to enunciate positive and unalterable rules of technique, yet to avoid injury and accomplish good several important points must be considered.

No one wishes to produce a violent dermatitis; yet it is the easiest thing in the world to do this, and occasionally it is not very easy to prevent it.

To be forewarned is to be forearmed, and the beginner in *x*-ray work ought thoroughly to appreciate the fact that susceptibilities to *x*-ray effects vary as widely as to other physical influences. We do not question the existence of idiosyncrasies in relation to the direct action of the sun's rays. to various external and internal methods of treatment, to psychical influences and even to the food we eat for the preservation of life. Nevertheless, it has been frequently stated that idiosyncrasy is a negligible quantity in the use of the *x*-ray both in diagnosis and therapeutics.

Unpleasant and unsatisfactory results are too often ignored in many an elaborate clinical report. Failures as well as successes, injuries inflicted as well as the good accomplished, should be frankly told.

In this way and in this way only can any medical or surgical procedure be perfected, with conservation of the best interests of both physician and patient.

While the condition and position of the tube and the time of exposure are the essential features *x*-ray treatment, yet, with every ordinary p caution, cases are sometimes met which defy th all, and a violent dermatitis suddenly breaks fo As an interesting and instructive illustrative c I refer to a patient sent to me for *x*-ray treatm by Dr. V. P. Gibney. Miss M. had suffered l and severely from a constitutional tuberculous c dition chiefly affecting the spine. Her pain a deformity had been greatly relieved by orthope treatment, but subsequently the glands of the n became permanently enlarged. With a tube medium penetrating power and a shield protect the surface surrounding the two enlarged glan the treatment was begun January 27, 1903. distance of the tube was eight inches and the ti exposure five minutes.

This treatment was repeated on the 31st i and on February 3 and 7, resulting in not the sli est symptom, objective or subjective. A new t of somewhat greater penetrating power now placed the old one, and in order to bring the lo part of the face, which was distinctly nodular a hard, within the field of exposure, the shield dispensed with. On February 12 the treatment of five minutes' duration, at a distance of six inch February 15, time, eight minutes, same distan February 19, time, ten minutes, same distan February 24, time. ten minutes, distance f inches.

With the exception of some slight itching, symptoms had been observed. but on the morni following the last application, an intensely acti and painful dermatitis suddenly developed.

This did not go on to the stage of actual necros but there was widespread destruction of epiderm associated with profuse watery discharge. Th corium itself was evidently somewhat involved, that when perfect healing took place after t lapse of two or three months, the new skin form tion was distinctly lighter in color than the ol which was perceptibly tanned. It remains to s that even this brief treatment was more or le effective in reducing the local pathological co dition. The deposits along the angle of the low jaw entirely disappeared, while the glandular e largements decreased perceptibly in size.

Aside from indicating a marked susceptibili to the effects of the *x*-ray, this case is a stro argument in favor of the cumulative theory *x*-ray action.

In no other way, it seems to me, than by this co bination of idiosyncrasy and cumulative action, c we explain the fact, that after carefully conduct *x*-ray exposures extending over a period of o month, with no preliminary symptom of itching burning worthy of mention, a violent and persiste dermatitis appears with hardly a note of warning.

Although a number of slighter burns have occurr in the personal experience of the writer—and, inde in a large proportion of cases it is quite impossible succeed without exciting more or less surface redn and irritation—this is the only case in which, wi every ordinary precaution, there was so severe after-result. However rare such cases are, yet th do occur with sufficient frequency to demand c stant watchfulness. Better far prolong the tre ment than to run even a remote danger of an act necrosis.

Above all, never fail to interrogate each patie as to any special idiosyncrasy, such as to sunbu to ivy poison or to any external application. a recent article on "The *X*-ray and the Finsen Lig in the Treatment of Lupus,"* I alluded to a case

*Medical Record, April 11, 1903.

such unusual susceptibility that the patient was compelled to abandon *x*-ray treatment for the actinic rays of light.

In this case, even when no appreciable dermatitis was evident, the slightest exposure caused most unpleasant sensations of burning and itching. In that article, however, I neglected to say that this patient told of a susceptibility quite as marked to the influence of the poisonous ivy. I afterward learned that she had been three times poisoned in this way, and on two of these occasions she had not even been in contact with the ivy leaves or vines.

I agree with Freund, that in every case, without there are most important reasons for haste, there should be an interval of rest after the first two sittings. I would suggest that these first two sittings be three days apart, with an interval of ten days before the third sitting, one week before the fourth, and four days before the fifth. If, in one week from the last exposure, there is no severe reaction, it will, I think, be perfectly safe to give treatment every other day and perhaps daily.

This method may to some seem an unnecessary precaution; but if the usual precautionary measures even occasionally fail, unusual ones, while perhaps burdensome, cannot be called unnecessary.

Especially are they not unnecessary—if interrogation on the points already alluded to shows evidence of any special idiosyncrasy. "A burnt child dreads the fire," and in all cases of superficial non-malignant skin diseases, at least in acne, in eczema, in favus, in sychosis, in hypertrichosis, etc., extreme precaution should be the beginning and end of *x*-ray interference.

The treatment of advanced malignant conditions is quite another matter. A burn, even of some severity, may be of small account relatively; but in simple, uncomplicated skin affections of a benign character, a pronounced dermatitis of the second or third degree might be regarded as worse than the disease itself.

35 East Forty-fourth Street.

LIQUEFIED AIR.*

By A. CAMPBELL WHITE, M.D.,
NEW YORK.

Only quite recently the writer gave a clinical demonstration of the treatment of an inoperable intrauterine carcinoma with liquefied air at one of the hospitals of this city before a number of physicians. I was not only impressed by the lack of knowledge displayed by almost all of those assembled as to the uses to which liquefied air might be applied in medicine and surgery, but was astonished to find such complete ignorance of the physical properties of the liquid itself. Hardly anyone present had ever even seen liquefied air before. Many had heard of its successful use in treating carcinoma and lupus, but did not appreciate that it had any possibilities in combating other more benign and more frequent lesions the body is subject to.

I am impressed with the fact, through association with physicians socially and in hospital and private practice, that this destitution of knowledge as to the physical properties and possibilities of liquefied air is not peculiar to the body of men before whom I gave the demonstration on the intrauterine carcinoma, but that only a very limited number of our profession understand or have ever seen this wonderful product.

There are many reasons why liquefied air is not generally better understood, why it has been considered dangerous, and why it has not been given a more extensive use in the alleviation of diseases. It would be infringing upon time and space to describe these reasons here. But the writer believes this an opportune time (now that liquid air can be obtained in sufficiently large quantities to be of general service) to give a brief description of the method of its manufacture, its physical properties, and to what uses we can put this agent with and without the aid of the Röntgen and ultraviolet rays, in the practice of medicine and surgery.

At a certain temperature and with a certain amount of pressure exerted upon a gas, this gas will enter into a liquid state. This temperature at which a gas can be liquefied is called the critical temperature of that gas, and the amount of pressure which is required to liquefy the gas at its critical temperature is called the critical pressure of that gas. Pressure alone does not reduce air to a liquid state, neither does a low degree of temperature alone make a gas a liquid. The critical temperature and critical pressure of air must be attained, then the air, a mixture of two gases, nitrogen and oxygen, becomes a liquid. The critical temperature of nitrogen, which is about three-fourths of the weight of the air, is 231 degrees below zero. The critical temperature of the mixture of these two gases (air) is 220 degrees below zero, therefore when air has been reduced to 220 degrees below zero, if the critical pressure is placed upon it, the air will liquefy. The amount of pressure required is from 1,500 lbs. to 2,000 lbs. to the square inch. To obtain the requisite amount of pressure is a simple task, but to obtain the required low temperature, 220 degrees below zero, has always been the stumblingblock to success.

It is well known that gas is cooled by expansion and upon this principle depends the success of the so-called Tripler and Linde methods of liquefying air. The natural air is compressed to the extent of 2,000 lbs. to 2,400 lbs. to the square inch. This is allowed to escape and pass through small openings, each protected by its own valve, into tubes which coil upon themselves over and over again, thus continually cooling off more and more the air as it enters the liquefier. These coils of tubes are what constitute the liquefier. This compressed air, now reduced to an extremely cold temperature, is allowed to escape into a vacuum, where it can readily be seen an extreme and sudden expansion must result. In this way the two necessary conditions are obtained, critical temperature and critical pressure. The result is that the liquefied air pours from the liquefier just as water does from a faucet; and, by the way, the method of drawing the air from the liquefier is just the same as turning the water on from an ordinary faucet, and the appearance of the liquid as it comes from the outlet is almost identical to that of hot water drawn from an ordinary faucet.

Sometimes natural air is cooled to 32 degrees below zero before entering the liquefier. This is not done to assist in reducing the temperature of the air so much as to freeze all the moisture in the atmosphere in order that ice will not form in the liquefier itself, which would tend to interfere with the proper action of the delicate valves which play so important a part in the reduction of the air to a liquid condition.

I have mentioned that the liquid air as it comes from the liquefier looks like hot water. Under nearly all conditions as we look at liquid air it appears hot, *i.e.* boiling. Why should it not boil? It is 400 degrees colder than anything with which it is likely to come in contact. The temperature of liquid air is 312 degrees below zero and the temperature of any receptacle we may pick up to contain it is about the temperature of the room, something over 70 degrees above zero. This makes

*In all mention of temperature in this article the Fahrenheit scale is referred to.

the receptacle about 400 degrees hotter than the liquid which enters it; the liquid therefore quickly boils away, thus entering into its original gaseous condition, the air we breathe, minus probably all of its former impurities.

Upon the boiling point of liquid air and the difference in the boiling point of its two ingredients, nitrogen and oxygen, undoubtedly depend a great deal of the usefulness of this product in medicine and surgery. On account of this difference in the boiling point the nitrogen and oxygen become largely separated as the liquid evaporates or boils. The boiling point of liquid nitrogen is 317 degrees below zero. The boiling point of liquid oxygen is 295 degrees below zero, and of liquid air 312 degrees below zero. Therefore the nitrogen must first boil away, leaving behind almost pure liquid oxygen. By apparatus based upon this principle the two gases can thus be separated, although there are other methods of separating them, and either gas or both combined, used at the discretion of the physician.

An interesting and simple experiment well illustrates this fact. If fresh liquid air is poured into an ordinary cut-glass tumbler and a lighted match is dropped into the liquid, the match will only burn as in the ordinary air, whereas if the liquid is allowed to boil for a few minutes, a steel needle to which a lighted match is attached when dropped into the liquid, will melt into a small ball which can be crushed into almost nothing between the fingers. As the steel is melting it gives off brilliant and noisy sparks, thus proving the residue of the liquid in the glass to be nearly pure oxygen.

When we consider it requires approximately 2000 degrees of heat to melt steel it seems impossible to believe that these two extreme temperatures, 2000 degrees above zero (melting steel) and 312 degrees below zero (liquid air), can exist at the same time in the same glass. Nevertheless it is true.

If it were impossible to prevent in some way this rapid boiling away of liquid air, as soon as it is made, its use from any practical standpoint would be limited to almost nothing. To confine it by main force would require cylinders of such strength and thickness as to be prohibitive, and the liquid would be confined under such great pressure that it would be impossible to withdraw it in the form of a liquid, the expansion being so great. Thus the only means of controlling the liquid was found to be by keeping its temperature just below its boiling point. To do this of course it was necessary to prevent radiation of heat, and as glass and a vacuum are both poor conductors of heat, both the glass and the vacuum are used for this purpose and in the following way: Two glass bulbs are made, one within another, the hermetically sealed space between the two bulbs being a vacuum. The surface of the inner and outer bulbs is also silvered, thus preventing the entrance of light and stopping further radiation of heat to some extent. The opening of the bulb can be closed with a felt stopper, allowing only slight evaporation of the air. Such a bulb is called the Dewar bulb. The Dewar bulb to give satisfaction should have a capacity of from four to five quarts, and the vacuum should be as nearly perfect as possible. No American manufacturer has yet succeeded in making these bulbs so as to keep the air any length of time, but the Dewar bulbs, imported from Germany, frequently are found to be so perfect as to contain the liquid without any boiling whatever, simply a slow evaporation, and I have seen air thus kept for many weeks. The Dewar bulb is the main factor in rendering liquid air of practical utility in hospital and private practice. Without it, or something to take its place, liquid air would be of little, if any service to us.

It is so universally considered that liquid air i an explosive that something should be said upo the subject. Liquid air is just as much an explosiv as steam, and no more so. If steam were confined if there were no safety valves to the boiler, it woul explode. Under the same conditions liquid ai would explode. Liquid air in an open vessel is n more likely to explode than steam is likely t explode in a teapot on the stove. In fact, liquid ai can be put in a teapot and placed upon a red-ho stove with as much impunity as water.

A lighted match dropped into liquid air cause no explosion. An electric spark can be passe through liquid air and no explosion results. I fact I know of no way of making liquid air explod other than could be used in making steam explod Alcohol frozen by liquid air is a violent explosive If frozen by any other means it would be equall as violent an explosive. It was an explosion o alcohol frozen by liquid air which caused seriou injuries to some people a number of years ago in public house, which probably did more than any thing else to propagate the idea that liquid air wa an explosive.

It is proper, also, to mention that any substanc soaked in liquid air is highly inflammable until th oxygen has entirely evaporated.

Liquid air at rest in a transparent Dewar bul has the appearance and color of the atmosphere i the distance on a clear day. Its weight and specifi gravity is approximately the same as that of wate and it obeys all the laws of fluids.

Possibly I have not emphasized sufficiently th fact that liquid air contains positively no moisture Of course, no moisture could exist in liquid ai without immediately being converted into a bod more solid and dense than ice. This fact is of n little importance to us in considering its use. It i hardly necessary to state that liquid air properl brought in contact with the tissues of the bod immediately freezes those tissues, the extent of th freezing depending upon the force with which i strikes the parts, the amount of liquid air comin in contact with the tissues, the degree of approx imation to the tissues and the duration of exposure The amount of slough consequent upon its applica tion varies from none whatever to as much as i desired, depending upon the previously mentione conditions of freezing, and whether or not the part frozen are incised. After an incision even sever freezing is not followed by a slough, for reasons whic will be given later.

If liquid air freezes the tissues, it goes without say ing, that it must be a local anæsthetic, yet I am fre quently asked whether it is or not. It is not onl a local anæsthetic, but as much or as little anæsthesi as is desired can be produced in three seconds' time The anæsthesia lasts longer and is followed by les slough than obtained by any other freezing mixtur because of its perfect freedom from moisture. I can be applied either with a swab or by a spray and limited to any area desired. When the liquefie air is applied to the skin it becomes perfectl anæmic. This is usually followed by a blush du to secondary congestion. This redness will be th nearest approach to sloughing following an applica tion, providing an incision is made, as an incisio relieves the congestion. If no incision whatever i made, the frozen part becomes elevated and look like an urticarial spot, and also resembles urticaria in that it becomes somewhat itchy. If the freezing has been sudden and severe this spot develops into a painless and non-sensitive bulla.

There is no pain attending the application as an anæsthetic, and the anæsthesia due to the paralysis of the nerve endings lasts from thirty to forty minutes. After the degree of anæsthesia desired has been obtained, a minute or more, depending upon how much the parts have been frozen, should be allowed to elapse before cutting, as the tissues are frequently too hard for satisfactory operative procedure immediately after being frozen. If the local anæsthesia is applied preliminary to the opening of an abscess or pus cavity of any kind, this delay in cutting should always be allowed, and after thorough incision and evacuation of contents of abscess it is well to spray into the cavity, particularly if a bubonic abscess, some liquid air which has been standing for a few moments. This spray, being almost pure oxygen, has a particularly salutary effect, and this freezing of the inner walls of the abscess promoting slough, making curetting of the cavity unnecessary.

It seems hardly necessary to go into detailed descriptions of the abnormal conditions of the skin and subjacent structures to which liquid air applications can be of service; for if we thoroughly understand the physical properties of this fluid the mere mention of the lesion to which it can be or has been applied, suggests a successful result. With such a competent knowledge of the physical properties of liquid air and its component parts, nitrogen and oxygen, we know it must have the power to accomplish at least the following results:

(1) Produce local anæsthesia, because it freezes. (2) Reduce inflammation: whenever cold is indicated, and in this case either the vapor or vessels containing the liquid, or the liquid air itself, can be used, depending upon the degree of cold desired. (3) Produce inflammation, and therefore local stimulation by producing a perfect localized anæmia, which is always followed by congestion. (4) Produce a slough, by causing an obliterating endarteritis and destruction of the nerve supply in a growth, by repeated freezings. (5) Antiseptic; although liquid air does not destroy pure and virulent culture of germs, it aborts their activity for a time, and with the assistance of the local congestion of the parts following the use of liquid air, nature easily overcomes and destroys their activity. (6) Produce oxygen—either in liquid or vapor form.

Any inflammatory process, where cold applications in any form is a desirable part of the treatment, can be administered to more satisfactorily and pleasantly with some method of liquid air in application than in any other way we have at our disposal. For example, an inflamed knee or other joint can be exposed to the cold dry vapor emanating from a vessel of boiling liquid air, and any degree of temperature can be given, and the temperature of the joint or part being treated, can be reduced to any desirable point. Another method, quicker in its after effects, is to soak a towel in the liquid and apply quickly and intermittently to the joint until it has been thoroughly chilled. A glass bulb filled with the liquid and rolled over the surface of the joint is another efficient means of accomplishing the same result. This latter method is particularly applicable in endeavoring to abort acute adenitis, periostitis and other inflammations. A current of air can be sent through the ice coil, providing there is protection between the coil and the skin, to great advantage when cold is a desirable adjunct in the case of acute abdominal troubles, such as appendicitis.

To produce an inflammation or stimulating effect the liquid air must be applied directly and intermittently to the skin. The best example of this effect is seen in chronic indolent ulcerating surfaces, when by spraying here and there over the surface, just sufficient to freeze for a second only, a good, healthy granulating surface will be obtained after only a few treatments of this character.

It can readily be understood that any foreign growth upon the skin or within reach of operation can be destroyed by liquid air. It may take two, three, or more applications. The only dangers to be avoided are excessive freezing, which results in inflammation which, though simple, can be much more than desired, and even result in more slough than wanted. The air inflammation subsides quickly and responds readily to hot boracic acid or carbolic fomentations. If such a growth as a nævus or any birthmark or fibroid tumor is treated judiciously it can be removed much more quickly and with less pain than by any other method. If not done too rapidly, no scar whatever is left to show its former location. The same applies to almost anything from an acne pustule to hæmorrhoids within reach of the spray tube. And here it might be mentioned that not even in extremely vascular nævi or hæmorrhoids need there be any fear of subsequent hemorrhage. I have removed a large scirrhus inoperable carcinoma of the breast with liquid air applications. This patient suffered from very severe hemorrhages as frequently as two and three times a week. From the time of the third application of the air there has never been a sign of a hemorrhage, and the same can be said of all other growths thus treated. I believe this is due to an obliterating endarteritis due to the treatment. In many of these growths I have found a discreet use of the Röntgen ray of undoubted assistance, particularly where the slough is likely to cover a large surface.

I believe liquid air must assist nature in overcoming a localized infection in somewhat the manner mentioned before, for in the treatment of carbuncles not too far advanced, not more than three inches in circumference, liquid air seems to act as a specific. In all the cases treated under this size, activity has been aborted apparently within one hour after a thorough freezing. In cases covering a larger area, it has been deemed desirable to incise crucially after it has been frozen, and then the cavity thoroughly sprayed with liquid oxygen. In those cases not incised, there have been natural openings through which the contents of the abscesses oozed freely during the stage of congestion following the freezing. This stage of congestion is exceedingly painful and lasts from twenty to thirty minutes, and should be alleviated by giving at least one-half grain of morphine previous to freezing.

If liquid air could be of service to the medical profession in the treatment of no other form of disease than carbuncle, its success in the treatment of this one lesion would be a sufficient reward for its discovery.

Almost as much can be said in favor of the utility of liquid air in the treatment of lupus, particularly lupus vulgaris. In the treatment of the vulgaris form of the disease, the liquid should be used freely and in the form of a spray. Here some inflammation is expected and desirable, the object being to transform the tubercular ulcer into a simple healthy ulcer, which is amenable to ordinary treatment. The Röntgen-ray treatment is neither a desirable nor necessary adjunct in the treatment of this form of lupus, but in the erythematous variety I believe the ray is of much benefit, applied not so frequently as to cause a burn. Here the liquid air should be applied moderately, and only to an

extent sufficient to cause gradual desquamation. By this method of treatment, although much slower, an excellent result is obtained without any resultant scar tissue.

To describe what has already been done, and the possibilities of the future, in making practical use of the vapors given off by boiling liquid air, opens up a broad field for study and deserves separate consideration. It can readily be seen of what great value a stream of cold, dry liquid oxygen, carrying with it any medication desired, would be in the treatment of such diseases of the air passages as hay fever, laryngitis, bronchitis, asthma, etc.; and again there is no reason why a liquid-air bath could not be given for the reduction of temperature in febrile conditions, and at the same time increasing or diminishing the percentage of oxygen according to the amount of stimulation desired.

To recapitulate: In liquid air we have the nearest approach to absolute zero ever obtained, excepting liquid hydrogen, which is many degrees colder and is liquefied by the assistance of liquid air. If there is any therapeutic value in cold we certainly have it in liquefied air, 312 degrees below zero, and from this we can obtain any desired temperature above that point. If there is any therapeutic advantage in having a dry cold, we have it in liquid air, for in anything colder than 32 degrees below zero no moisture can exist. That moist cold is more destructive to the tissues than dry cold, is an accepted fact. If it is desired to produce a local anæsthesia by cold, we have no means of obtaining the result equal to liquid air, for it is dry, rapid, thorough, clean, and under perfect control. That circulatory changes can be produced by the extremes of temperature, that of liquid air and the human body, is self-evident, and experiments in this direction have demonstrated its therapeutic value both in the production and reduction of inflammation, according to the method of its use. Being nothing but the air we live in, reduced to a low degree of temperature, and free from the usual pollutions of the atmosphere, it surpasses all other applications previously in use for the removal of all growths of benign or malignant character, because its application is practically painless, its action more rapid than electrical methods, and there is no systemic effect whatever following its local use.

If there is any value in the therapeutic use of oxygen, we have it in its most concentrated form in liquid air, from which it has been demonstrated we obtain liquid oxygen, and oxygen of much higher percentage and purer quality than obtained in any other way.

As I have mentioned before, if the medical profession really understood what liquid air is and what physical properties it displays, its therapeutic value would at once appeal to them. To understand thoroughly just what liquid air is, remember steam is water or liquid at any temperature below 212 degrees above zero, so is air a liquid at any temperature below 312 degrees below zero. If steam had been known to us before water, water would have been called liquid steam. As we have always known air as a gas, in its liquid state we call it liquefied or liquid air. It is the air we breathe, in a liquid form, just as water is steam in a liquid form.

To Exterminate Malaria in Austria.—The Austrian Government has undertaken to exterminate malaria on the coast of Istria. Several stations have been established at which quinine is furnished free and patients are carefully screened so as to prevent mosquitos from spreading the infection.—*The Evening Post.*

A CASE OF PRIMARY CARCINOMA OF THE LUNG DIAGNOSED FROM THE EXPECTORATION.

By FREDERICK F. C. DEMAREST, M.D.,
PASSAIC, N. J.

On March 18, 1903, Mr. C. W. called at my office, complaining of hemorrhage from his throat and pain in the right side of his chest. The patient was forty-two years old, well-nourished, weighed one hundred and fifty pounds, was five feet nine inches high, had a normal temperature with a pulse of eighty, and respirations of twenty-eight per minute.

Physical examination showed practically a normal condition of his nose, throat, and larynx, with a pool of blood lying in the trachea, at its bifurcation.

There was an area of consolidation corresponding to the upper one-third of the right lung.

Patient gave the following history: Denied all history of syphilis; appetite and digestion were good. He said the hemorrhage from his throat had occurred daily for the last nine months to the extent of about a tablespoonful of pure blood in twenty-four hours. He had been examined two years previously, at which time he was advised that his temperature was normal and that there were no bacilli in his sputum; but he had an area of consolidation at the apex of his right lung, and he was instructed to go to the Adirondacks, which he failed to do.

On March 20 he came to my office and handed me a glass jar, which contained a tablespoonful of clotted blood, and a lump of tissue about a half of an inch in length and a third of an inch in thickness, which he stated he had "just coughed up." This specimen, a slide of which is now in my possession, was taken to Dr. H. T. Brooks, and pronounced by him to be typical squamous-celled carcinoma.

I advised my patient that his trouble was a fatal one, and that the only possibility of relief in his case was that connected with *x*-ray treatment, but that I did not think such treatment would effect any cure. He, however, insisted that the treatment be tried. The patient being a merchant, who had Chicago connections, he decided to go to Chicago to make some business arrangements, and then return to me for the *x*-ray treatment.

On April 9 he returned from Chicago to me for his first treatment, at which time I noticed he exhibited a slight lack of coördination connected with his right arm and leg, *i.e.* metastatic involvement of the left side of his brain. I gave him fifteen-minute exposures at twelve inches every third day over his right lung until May 21, at which time his leg and arm became so unmanageable that I considered it unwise to have him brought to my office any longer for treatment. His hemorrhage had decreased until he expectorated only about a drachm of blood in twenty-four hours; all pain had left his right side, and the fluoroscope showed only one-third of the shadow which was seen on April 9, and his temperature was still normal.

I saw him at his home until his death from paralysis of the heart on July 2, during which time he expectorated daily a small quantity of bright blood and shreds. He ate three meals a day and digested them perfectly and suffered no pain, dying suddenly after a very comfortable day. No autopsy was secured.

This case is reported on account of its peculiar features, viz., chronic hemorrhage for nine months, continued normal temperature, absence of emaciation, and because I believe it to be the second case on record in which carcinoma of the lung has been diagnosed from the expectoration.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THOMAS L. STEDMAN, A.M., M.D., ASSOCIATE EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, January 16, 1904.

PREVENTION OF TYPHOID FEVER.

IN most of the larger municipalities of this country typhoid fever is to-day an endemic disease. In our smaller cities and rural districts its epidemic appearance is not of infrequent occurrence. These facts have been the occasion of considerable comment both in the lay and medical press. Without doubt they are worthy of careful consideration. Since contaminated milk or water supplies are the chief avenues along which the infection of typhoid fever is transmitted, municipal and State authorities, in their fight against this disease, have principally directed their attention toward safeguarding these channels against contamination. When we consider the country at large there can be no question but that the measures thus instituted have been in a marked degree effective. If this were not so the frequency of typhoid fever would equal or exceed that of any other bacterial disease with the possible exception of tuberculosis. If, however, when taken collectively the work of the authorities in this direction deserves praise rather than criticism, it is, nevertheless, true that at times typhoid epidemics develop in communities in which these preventive measures have not been properly put into execution. Such epidemics usually occur in our smaller cities and rural districts. In many of these the health and other official departments are incompletely and insufficiently organized. They are therefore unable to put into operation means which have proved efficient in large municipalities where organization is much more complete. If this is true, and it can be substantiated by careful investigation, the blame for the contaminated milk and water supplies is not so much to be attached to the individuals in office as it is to the conditions under which they are forced to perform their work. It follows, therefore, that the greatest need at the present time is a thorough reorganization in the smaller cities and rural districts of the departments under whose direction these measures of prevention must be carried on. Only in this way is it possible to bring them up to the requirements and place them in a position where they can be reasonably expected to exercise the degree of vigilance which is necessary.

After all has been said upon this phase of the subject which can be said, the fact still remains that the cause of the prevalence of typhoid fever, either in its endemic or epidemic form, is not to be found in a contamination of the water, milk, or other food supply. These are usually the avenues along which the infective agent is conveyed. The cause lies back of this. It is none other than the failure to destroy the causative bacillus as, by various routes. it leaves the bodies of those suffering from the disease, Measures directed toward this end lie essentially outside the province of officials and come directly within the sphere of the medical practitioner. It cannot be doubted but that the medical profession realize this necessity, and in the majority of instances institute such measures so far as they understand them and so far as the circumstances which surround each case permit It has recently been said that the institution of such measures is usually a farce. Any such statement as this is not only untrue, but it is a direct libel upon the honesty and intelligence of the medical profession. If this statement were true the dissemination of typhoid bacilli would be so great that the prevalence of the disease would necessarily be greater than it is. And this would be so in spite of the most careful action of the authorities in safeguarding the avenues of infection. All admit that the disinfection which accompanies a case of typhoid fever is usually insufficient, but this is very different from saying that it is a farce—which means that it is a ridiculous sham. Nor do we believe that this insufficiency of disinfection in typhoid fever is due to the widespread use by the medical profession of any patented brand of disinfectant which is lacking in bactericidal power. For if such a disinfectant were in widespread use the results of its employment would be *nil*. This would mean a much greater dissemination of typhoid bacilli than can be reasonably supposed to take place. In looking for the routes by which the typhoid bacillus leaves the body we find that they are principally two: the fæces and the urine. The bacilli are most abundant in the fæces at the height of the disease. From this time on they become reduced in numbers. At the time when convalescence is reached they are usually absent. Exactly the reverse holds true for the presence of the bacilli in the urine. Here they usually first appear during defervescence. In convalescence they reach their greatest numbers. In many cases they are present in the urine for weeks after recovery. The disinfection of the fæces has received time-honored consideration. That it is efficiently carried out in the majority of cases of typhoid fever cannot be doubted. The disinfection of the urine is of more recent occurrence. Investigation will show that at the present time if the urine is disinfected at all this is only practised during the disease or at the best only until convalescence is established. There is no doubt whatever but that in many instances those who have recovered from typhoid fever go about voiding urine which contains typhoid bacilli and that this is by far the most frequent means of the dissemination of these organisms from these patients. The realization of this condition and the institution of the proper means for combating it by the medical profession is the crying necessity.

The prevention of typhoid fever at present, therefore, requires the consideration of two factors: (1) The destruction of the causative bacillus as, by various routes, it leaves the bodies of those suffering from the disease. (2) The safeguarding of the avenues of infection. The first and most important is to be accomplished by the physician. The second requires the attention of the authorities. Neither

of these objects is to be accomplished by slander or incrimination. Education and organization are rather the watchwords.

THE LATEST VIEWS ON CANCER.

THE greater part of the issue of the *British Medical Journal* of December 12 is given over to a consideration of the cancer problem. The matter is threshed out more or less thoroughly by some of the most eminent British authorities on the subject.

The first original article in the journal referred to, is the Bradshaw Lecture delivered this year by Mr. Henry Morris. Among other reasons which the lecturer gives for choosing cancer as his subject is that "the premature publication of immature and disputable conclusions, and of crude and impossible theories has unfortunately aroused false hopes, and has attracted the impatient and somewhat credulous attention of the general public to everything connected with the word 'cancer.'" It would be well, Mr. Morris thinks, if it were possible to allay these consequences.

The various theories as to the origin of cancer, both carcinoma and sarcoma, are then reviewed. The theory, however, that the author himself believes destined to be accepted as the true explanation of the genesis of malignant new growths is that which was put forth by Durante of Rome about the year 1874, and a year or two later by Cohnheim. Mr. Morris deems this theory more consistent than any other with all that we know about malignant diseases, and which fully explains the origin of the very many non-malignant tumors.

Cohnheim's view was that the origin of carcinoma was due to the proliferation, not of mature but of embryonic epithelial cells. He held that all tumors originate from a matrix of embryonic cells which during fetal life are cut off from their proper connections, remain in an undeveloped state, are surrounded by developing and ultimately developed tissues, and thus become, so to speak, "embryonic inclusions."

The deficiency of this theory, according to Mr. Morris, is that it does not explain the formation of malignant new growths in scar tissue, in immature callus, in unabsorbed inflammatory products, and in parts after injuries and operations of various kinds. To meet this deficiency Senn added the following corollary: "The tumor matrix may be composed of embryonic cells, the offspring of mature cells which have failed to undergo transformation into higher tissue, and which may remain in a latent, immature state for an indefinite period of time, to become, under heredity or acquired exciting causes, the essential starting point of a tumor.

Mr. Morris examines separately, the evidence in favor of the separate parts of the "tumor germ" theory, namely: (1) The existence of congenital matrices of embryonic cells. (2) The existence of matrices of post-natal formation. (3) The continuance of these matrices for a time in a dormant state. (4) The causes which arouse the matrices into activity. The lecturer accomplishes his task with much success and presents a strong case for the tumor-germ theory. He also places his finger upon the weak spot in the investigations as to the cause of cancer which have been carried on for the past ten or fifteen years. These researches have been too exclusively directed to microbes and too little to cancer. It short, Mr. Morris is of the opinion that the microbic theory of the origin of cancer is decidedly losing ground.

The parasitic theory of the etiology of cancer is excellently set forth and championed by Mr. H. G. Plimmer. Among other strong evidence in support of this theory he mentions Behla's view that cancer is frequently conveyed by uncooked infected vegetables. Dr. Lyon's figures with regard to cancer in Buffalo for a period of twenty years are also quoted as confirmatory of this idea. Statistics showed that roughly for the same population, the cases of cancer in the German wards of Buffalo were double the number of those in the native, due, in Dr. Lyon's opinion, to the fact that the Germans were in the custom of eating uncooked vegetables.

Many other points tending to substantiate the parasitic theory are advanced by the writer.

Mr. G. Lenthal Cheatle, who contributes an article in which he discusses the behavior of cancer within nerve and trophic areas, is almost confirmed in the truth of a suggestion he put forward some time ago. That a possible direct or indirect nervous influence is the chief agent in directing the areas occupied by cancer, and is responsible for its spread. His reason for this belief among others, is that it is impossible to omit the subject of irritation from among the etiological factors of cancer.

Dr. Arthur Newsholme, in his article, endeavors to trace the possible association of the consumption of alcohol with excessive mortality from cancer. The following figures are given of death rates in Great Britain in support of this view. The death rate from all causes in the three years, 1891, 1986, and 1901, was 17.13 among the abstainers, and 23.52 per 1000 lives at risk among non-abstainers; while the death rate from malignant disease was 0.95 among the former and 1.32 per 1000 among the latter. In other words, if the death rate among non-abstainers in each instance be stated as 100, that of abstainers from all causes was 72.8, and from cancer was 72.0. Notwithstanding these statistics Dr. Newsholme concludes "that evidently, however, if alcohol exerts an irritating effect, this is only one of a number of conditions favoring cancer, and alcohol cannot be elevated to the position of a primary cause."

Dr. Dawson Turner and Dr. John Macintyre contribute papers on the physiological action and therapeutic effects of radium in the treatment of cancer, and Dr. Lovell Drage gives the results he obtained from the injection of a solution of sodium cinamate in glycerin.

The series of papers in the *British Medical Journal* illustrate in an extremely vivid manner both the extent of our present knowledge and of our ignorance regarding cancer, and especially as to its origin. Little headway has been made within the past twenty years, in spite of the time spent on the subject and the efforts put forth to solve the problems in connection with this deadly and loathsome disease—in unveiling its mysteries. The chief hope that this object may be accomplished lies in the fact that scientific men of all countries, spurred on by the interest taken in the question by rich and poor alike, are bending all their energies to the task in hand.

The X-rays and Radium in the Treatment of Cancer.

The Annus Medicus of the *Lancet* refers especially to the therapeutics of cancer, quoting from a paper published in the first volume of the "Archives of the Middlesex Hospital," by C. R. C. Lyster, the medical officer in charge of the electrical department of that institution. In writing of the effect which the *x*-rays have upon cancerous growths, the author says "that a very large number of cases have been relieved of pain, and that in a certain number the growth has undergone a definite retrogression; of all the new growths the rodent ulcers have been by far the most satisfactory to treat. The cases that have been under treatment have varied from those exhibiting small recent spots to the most extensive and old-standing lesions. They have all shown a great tendency to improve; the more recent ulcers have quickly healed, leaving a healthy scar, and there had been no recurrence up to the time of publishing the report. In cases of rodent ulcer of long standing, and with considerable loss of tissue the tendency to heal has been remarkable, but after a time, recurrence is not unusual, and this seems to be more difficult to deal with than is the original ulcer. Of other growths, experiments so far seem to show that the best results are obtained in cases of mammary carcinoma, especially in the recurrent forms. Sarcomata are not so amenable to treatment as are carcinomata. The cases which are apparently the least benefited are the epitheliomata, and this is more especially the case after secondary infection of the lymphatic glands has occurred. With regard to the use of high-frequency currents in malignant disease, it is believed that the good results claimed for this therapeutic measure are due more to the tonic action of the rays than to any direct action on the growth itself. Cases of rodent ulcer and epithelioma were submitted to the action of radium and also to pitchblende, the application of the latter substance being of particular interest, as it is far more easy to obtain than radium; the results of the treatment have not yet been published."

The *Lancet*, in reference to radium in the treatment of cancer, says: "Full of theoretical interest as the discovery of radium is, its remarkable property of radioactivity has already met with practical application in the treatment of disease, but its real value in this regard, as in the treatment of cancer and lupus, cannot yet be determined. The radio emanations are undoubtedly powerful to produce chemical change, but it remains to be seen whether they will be effective in checking the advance of a morbid process, or of destroying, or of restoring to a healthy state, diseased tissue."

The Vienna correspondent of the *British Medical Journal* of December 26 states that Exner and Hozknecht have used radium in the treatment of carcinoma and sarcoma with satisfactory results. The conclusions reached by these investigators are as follows: "Radium rays irritate the cells of the skin less vehemently than cells of cancer and sarcoma. The last named are brought to necrosis before the other tissues suffer severely from the effects. The radium dermatitis is very similar to the Röntgen rays dermatitis." The experience then of the majority of medical men who have used *x*-rays in the treatment of cancer is that in some forms of the disease they have proved decidedly beneficial. As to radium, its use has been too limited and the period in which treatment has been effected by its means has been too short to warrant the passing of a definite opinion with regard to its efficacy as a therapeutic agent in cancerous growths.

Typhoid Fever in Pittsburg.

Recent accounts give rise to the fear that Pittsburg may be on the verge of a serious epidemic of typhoid fever. During the past few weeks a large number of cases have been reported, and it would certainly appear as if the disease were making considerable headway. The mortality is also said to be high. As to the manner in which the malady has been conveyed to Pittsburg nothing is definitely known, although the assumption that there is a close connection between the epidemic at Butler and the occurrence of typhoid fever in Pittsburg is reasonable. The proximity of the two places, and the fact that many residents of Butler sought refuge in Pittsburg renders it extremely likely that the infection was thus carried. Be this, however, as it may, one point stands out with especial prominence, that immediate and adequate efforts must be put forth, both to drive out the disease from the infected cities, and to prevent the epidemic from spreading further. The field in that part of Pennsylvania is wide, and the soil is fertile for the propagation of typhoid fever, and unless prompt measures be taken, the results may be disastrous. In these days of enlightened and improved sanitation, it should be regarded as a crime to allow the dissemination of such a disease as typhoid fever. The means of preventing it are known, and a community has the right to view, with a certain amount of distrust, boards of health who are unable to safeguard its members against an epidemic. It is to be hoped that vigorous steps will be taken to protect uninfected districts from an outbreak of the disease. The lesson—that a pure water-supply and good sanitation generally are essential to preserve in health the inhabitants of cities and towns—has been so often taught in this country, and the results of neglect have been so terrible, that the indifference exhibited by the population, with regard to the matter, cannot but be characterized as remarkable. If the epidemics of typhoid fever now raging in the United States should have the effect of arousing its citizens to a sense of their danger, and of inducing them to insist upon proper sanitary regulations, the most dosirable of all reforms will be effected.

The Jubilee Number of the "Albany Medical Annals."

The Albany Medical Annals has celebrated its twenty-fifth anniversary by the publication of a "jubilee number." The issue is a notable one and reflects great credit on all concerned in its make-up. The articles therein contained are with no exception excellent, both in matter and composition. Drs. Frederic C. Curtis and Willis G. Tucker contribute a sketch of the inception and development of the journal. The first number of the *Annals* was sent out in 1880, the first editors and committee of publication being: Drs. F. C. Curtis, A. Vander Veer, J. B. Stonehouse, Lorenzo Hale, and J. D. Featherstonhaugh. Up to 1888 the *Annals* was conducted as a medical society journal, when the Albany Medical Library and Journal Association was founded, and it passed into their hands. In 1891 the *Annals* became a journal of the Alumni Association of the Albany Medical College, and as such has continued up to the present time. In 1897 the journal took on its present form.

In the current number are articles by Drs. Albert Vander Veer and Edgar A. Vander Veer, on "Four Cases of Gangrene"; by Dr. Samuel B. Ward, on "Lipoma of the Intestine:" by Drs. Henry Hun, George Blumer, and George L. Streeter, on "Myasthenia Gravis"; by Dr. Hermon C. Gordinier, on "Acute Ascending Paralysis of the Type of Landry";

by Dr. Joseph Craig, entitled "A Consideration of the Efficacy of Antitoxin in the Treatment of Diphtheria"; by Dr. Andrew MacFarlane, on "Nervous Dyspepsia"; by Dr. Richard Mills Pearce, on "The islands of Langerhans in Congenital Syphilitic Pancreatitis"; by Dr. H. Judson Lipes, entitled "A Study of the Changes Occurring in the Endometrium During the Menstrual Cycle"; by Dr. Arthur W. Elting, on "The Pathology and Treatment of Tetanus"; by Dr. Spencer L. Dawes, entitled "A Plea for the Rational Administration of Chloroform as a Routine Measure in Labor"; by Dr. Clement F. Theisen, on the "Etiology and Diagnosis of Ozena and Its Relation to Pulmonary Tuberculosis"; by Dr. Henry Larned Shaw, on "Starch Digestion in Infancy;" by Drs. Herbert D. Pease and Henry L. Shaw, on "The Etiology of the Summer Diarrhœa of Children and of Dysentery of Bacterial Origin"; and by Dr. Alvah H. Traver, on "Cysts of the Mysentery."

As said before, the contributions to the Jubilee number of the *Albany Medical Annals* are exceptionally good, and prove that themedical college, in the past and present members of its staff, possesses writers of no ordinary ability. The *Albany Medical Annals* has, in its twenty-five years of existence, amply justified the wisdom of its founders, and has shown that a local medical journal can be in its own sphere as useful and valuable as the national ones. Indeed the Albany publication enjoys now more than a local reputation, and may be termed one of the best monthly medical journals published anywhere.

News of the Week.

The Tuberculosis Congress Situation.—An informal meeting of American physicians and hygienists interested in the tuberculosis problem will be held in Baltimore on January 28, 1904. The object of the meeting will be to form a national committee to represent the American medical profession at the International Congress on Tuberculosis to be held in Paris in 1905. It is announced that there will also be a free discussion of the rival congresses on tuberculosis, that is to be held in St. Louis under the leadership of Mr. Clark Bell, and the other to be held in Washington in 1905 under the leadership of Dr. Daniel Lewis. All communications relating to this meeting should be addressed to the secretary, Dr. H. Barton Jacobs, 11 Mount Vernon Place, Baltimore, Md.

A New Journal.—The first issue of a new journal called *The Journal of Infectious Diseases* recently appeared. The new magazine is devoted to the publication of original investigations dealing with the general phenomena, causes, and prevention of infectious diseases. It has been established in connection with the Memorial Institute for Infectious Diseases, founded by Mr. and Mrs. McCormick in memory of their son, who died of scarlet fever. It is estimated that the annual cost for publishing this journal will aggregate $15,000.

Dr. Chas. F. Sanborn has recently been appointed Medical Inspector and Examiner by the Equitable Life Assurance Society, for the territory included in Minnesota, North and South Dakota, Wyoming and Manitoba, his residence being in St. Paul.

The American Society of Tropical Medicine held its first formal meeting in the auditorium of Houston Hall at the University of Pennsylvania on the evening of January 9. Dr. James Carroll of the United States army delivered an address entitled "The Etiology of Yellow Fever." Dr. Carroll was a member of the Army Medical Commission sent to Cuba a few years ago to study the causes and the mode of transmission of yellow fever, and as a result of whose investigations it was established that the disease is conveyed solely by the mosquito—stegomyia fasciata. This commission was composed of Dr. Walter Reed, surgeon U. S. A., Dr. Jesse W. Lazear, Dr. James Carroll, and Dr. Aristides Agramonte, contract surgeon. Of these the last alone was immune. Dr. Carroll and Dr. Lazear submitted to inoculation and both had attacks of yellow fever, from which unhappily the latter died. It was definitely determined that the bacillus icteroides of Sanarelli has no etiological relation to yellow fever, being merely a variety of the hog cholera bacillus. So also, the microorganism found by Finlay is an accidental and indifferent parasite. It was demonstrated that the disease is not conveyed by fomites, the only demonstrable medium of communication being the stegomyia that has sucked the blood of an infected person within the first few days of the disease, though only after an interval of twelve days and from that time so long as the mosquito may live. The period of incubation in man is about twelve days. The disease may be transmitted by means of the blood of infected persons directly, even after passage through a porcelain filter, but if the blood be heated to 55° C, it loses its infectivity. The evidence seemed to show that the blood-serum of convalescents from the disease has both prophylactic and curative value. As a result of the work of the commission of which Dr. Carroll was a member, yellow fever has been practically exterminated in Cuba. The rôle of the mosquito in the transmission had been previously suggested by others, but it remained for the commission to make its demonstration. The identity of the hypothetical microorganism is yet to be established. The officers of the American Society of Tropical Medicine are as follows: *President*, Dr. Thos. H. Fenton; *Vice-Presidents*, Drs. James C. Wilson and James M. Anders; *Secretary*, Dr. Jos. McFarland; *Treasurer*, Dr. E. Baldwin Gleason.

Assault on a Health Officer.—Dr. Thomas S. Faucette, Acting Superintendent of Health of Alamance County, N. C., was assaulted last Saturday at Haw River, N. C., while inquiring into the disinfection of houses that had contained smallpox patients. He was struck on the head with a rock by a man whose premises he was to disinfect.

The Taylor Memorial Hospital at Pao-Ting-Fu, China, erected by the Class of '82 of Princeton in memory of G. Yardley Taylor, who was killed in the "Boxer" uprising in 1900, has been entirely completed and is now ready for the reception of patients. The building covers a lot 54x28 feet, and is three stories in height.

Threatened Scarcity of Camphor.—One result of the imminence of war between Japan and Russia has been that the world's supply of camphor has been cut off, and in the event of war will probably remain so for an indefinite period. Practically the entire supply comes from Japan and Formosa, and about six weeks ago the Japanese Government placed an embargo on its shipment. The result has been a sharp advance in price, and while the scarcity has not yet been felt to any great extent, it undoubtedly will be as soon as the period of greatest consumption begins, in April. The reason for the embargo by the Japanese Government is that camphor is one of the necessary ingredients in the manufacture of smokeless powder.

A Health Commission to Tahiti.—Drs. H. Louvan, F. Cassian, and Grosfellez, members of a commission appointed by the French Government, recently sailed

from San Francisco for Tahiti, where they will endeavor to check the ravages of disease, especially leprosy and elephantiasis, among the natives.

Smallpox in West Salamanca, N. Y.—Upward of thirty persons at West Salamanca are suffering from a disease which has been diagnosed as smallpox. The health officials of Salamanca have established quarantine between the two villages, while the West Salamanca health officer is quarantining all cases. Scores of people have been exposed. In all but three or four cases the disease is in a mild form.

Typhoid Fever in Western Pennsylvania.—Grave fears exist that Kittanning, Pa., may have an epidemic of typhoid fever. On the first of December there were but four cases reported, but on January 4 there were one hundred cases, and the disease is increasing rapidly. So far the death rate has been small.

Dr. Sachs's Treatise on "The Nervous Diseases of Children" has been translated into Italian by Dr. Luigi Colombo of Varese, and a French translation of the same work is also in press.

Ohio Nurses to Organize.—A movement toward organizing a State Society of Trained Nurses, with the ultimate object of securing legislation for the advancement of the nursing profession, will take on tangible form at the convention which is to be held in Cincinnati, January 27–28. In addition to independent nurses all alumnæ associations, nurses' clubs and schools are expected to send delegates. The meetings will be held in the City Hospital amphitheater.

Dr. W. O. C. Harding of Elmwood Place, Ohio, has been reappointed Big Four surgeon for this district of the road. This is Dr. Harding's ninth year as surgeon to this railway.

War on the Spitting Nuisance has been declared by the new Health Commissioner of New York. Officers have been sent to the ferry-houses where the offence is most flagrant, and a number of the law-breakers have been arrested.

For United Action against the Plague.—A despatch to the *New York Times* from Berlin states that Great Britain, France, and Germany have sent official communications to Washington urging the United States to accept the results of the recent Sanitary Conference in Paris with a view to the prevention of the plague. The United States and Turkey were the only important countries not represented at the conference.

A Tuberculosis Exposition will be held in McCoy Hall of the Johns Hopkins University, Baltimore, during the week beginning January 25. The opening meeting will be held at 8 o'clock in the evening of that day. An address will be delivered by Dr. E. L. Trudeau of Saranac Lake. At 5 o'clock each afternoon after the opening day there will be a lecture upon one of the various aspects of the tuberculosis problem. The speakers will be Dr. Mazyck P. Ravenel of Philadelphia, Dr. S. A. Knopf of New York, Mr. Frederic Hoffman of Newark, N. J., Mr. Ernest Poole of New York, Dr. Vincent Y. Bowditch of Boston, Dr. George J. Adami of Montreal, and Dr. Lawrence Flick of Philadelphia. The exposition is organized under the joint auspices of the Tuberculosis Commission, the State Board of Health, and the Maryland Public Health Association.

"Illustrated Review of Physiologic Therapeutics" is the title of a new journal, the first issue of which is dated January, 1904. The editor is Dr. S. H. Monell and the publisher Mr. E. E. Peltor of this city. The present number is chiefly striking because of the number of well-executed pictures of apparatus, some good, some of questionable utility. There are a number of articles, some quite old, reproduced from other journals without editorial comment, but no abstracts from home or foreign periodicals. The claim is made that this is to be "a medical journal devoted to a review of the work of each month in the clinical uses of all electric currents, radiant energy, mechanical apparatus, heat, water, *x*-rays, the various rays of light, etc.," but the initial number hardly substantiates that claim.

The First French Congress of Climatotherapy and Hygiene of Towns will be held at Nice during the Easter vacation, April 4 to 9, 1904. Professor Chantemesse has been named president; the vice-presidents are: Drs. Renaut of Lyons, Grasset of Montpelier, Calmette of Lille, and Balestre of Nice. The discussions will bear on five questions: (1) "The climate of the French Mediterranean coast." (2) "Adaptation of the individual to climate." (3) "Influence of the French Mediterranean coast climate on tuberculosis and tuberculous patients." (*a*) "Clinical and critical discussion on the special conditions required in order to benefit by this influence;" (*b*) "Treatment of such patients at their home;" (*c*) "Treatment of such patients under supervision: Sanatoria for patients in easy circumstances;" (*d*) Establishments for the treatment of poor patients suffering from scrofula or pulmonary tuberculosis. (4) "The influence of climate on the French Mediterranean coast on rheumatism and on those subject to rheumatism." (5) "Disinfection of towns." Reduced rates on the railways will be granted to members of the congress and their families. The hotel prices at Nice will also be reduced in their favor. Particulars may be obtained from Dr. Hérard de Bessé, Secretary General of the Congress, Beaulieu-sur-Mer, France.

The Philadelphia Neurological Society.—The twentieth anniversary of the organization of this society will be celebrated on Tuesday, January 26, 1904. Papers will be read as follows: "The Metaphysical Conception of Insanity," by Dr. James Hendrie Lloyd; "The Mental Processes by Which the Rest-Treatment Was Developed," by Dr. S. Weir Mitchell; "The Surgical Operations Applicable in Insanity," by Dr. J. Chalmers, Da Costa; and "Mystic Medicine," by Dr. Francis X. Dercum.

College of Physicians of Philadelphia.—At a stated meeting, held January 6, Drs. David L. Edsall and Albert A. Ghriskey presented a communication entitled "Concerning the Transmission of Pneumonia, with a Report of a Small Hospital Epidemic." They reported a group of cases occurring in a series of patients who had occupied the same bed, or beds in close proximity, and some of whom, following the first case of pneumonia, also had pneumonia, while others had a general pneumococcic infection without pulmonary localization. Some of the latter cases occurred in patients already suffering from typhoid fever and cerebrospinal meningitis, and the general infection was discovered accidentally in the course of examinations made for other purposes. As soon as the epidemic character of the disorder was recognized, prophylactic measures were instituted, and there were no further cases after thorough disinfection with formalin. It was pointed out that pneumonia may be transmitted in three different ways: (1) By widespread aërial convection, a large number of cases occurring in widely separated portions of a community or district simultaneously without any other common channel of communication. (2) Through local infection, as, for example, the dissemination of sputum from one or more primary cases of pneumonia. (3) Direct contagion, in which infection occurs by immediate contact between a patient suffering from pneumonia or other pneumo-

coccic infection and the individual subsequently attacked. In view of the possibility of the epidemic spread of the disease, the recommendation was made that cases of pneumonia be included by boards of health among the list of notifiable diseases. Also steps should be taken in the individual case to secure isolation of the patient and disinfection of the discharges. Dr. Thomas R. Neilson exhibited a specimen of intussusception of the vermiform appendix. It was obtained from a child two and one-half years old that presented symptoms suggestive of intestinal obstruction. A diagnosis of recurrent appendicitis was, however, made, and operation performed. Dr. Joseph McFarland referred to a specimen of similar character that had been submitted to him for examination. It came from a child that had presented symptoms of appendicitis, the family declining to permit operative interference. After a while a large quantity of purulent material was discharged from the bowel, and in its midst was found a mass that on investigation was found to be the appendix in a state of intussusception. The following officers were elected for the ensuing year: *President*, Dr. Arthur V. Meigs; *Vice-President*, Dr. James Tyson; *Secretary*, Dr. Thomas R. Neilson; *Treasurer*, Dr. Richard H. Harte.

Vital Statistics of Philadelphia.—According to the annual report of the Philadelphia Board of Health, the death rate per thousand of population was 18.82 for the year 1903. The total number of deaths was 25,947, as compared with 23,847 in 1902. The greatest increase in the number of deaths is attributable to typhoid fever, to which 957 deaths were due, 372 more than in the preceding year. This increase is ascribed to pollution of the water supply and infection of the milk supply. Pneumonia was responsible for 3,180 deaths, as compared with 2,976 in 1902; pulmonary tuberculosis, 3,053, as compared, with 2,845 in 1902; smallpox, 278, as compared with 231 in 1902. The death rate was lower in the following years: 1902, 17.67; 1901, 18.26; 1899, 18.78; 1897, 18.72. There were reported during the year 8,650 cases of typhoid fever, 3,200 of scarlet fever, 3,043 of diphtheria, and 1,637 of smallpox.

A Dinner to Dr. S. Weir Mitchell was given on the evening of January 6, in Philadelphia, by the members of the Franklin Inn Club, in celebration of the anniversary of the birth of the namesake of the club, Benjamin Franklin. Dr. Mitchell is the president of the club.

Measles and Typhoid Fever in Cincinnati.—The number of cases of measles and typhoid fever in Cincinnati are increasing steadily. Health Officer Clark W. Davis reports for the week ending January 1, 171 new cases of measles, with 1 death, and 31 new cases of typhoid fever with 5 deaths. For the week ending January 2, 1903, only 2 cases of measles with 1 death, and 14 of typhoid fever with 3 deaths, were reported. Diphtheria, scarlet fever, whooping-cough, and varicella show a decrease over last year.

Dr. Charles Whitney Dabny has accepted the offer of the presidency of the University of Cincinnati. He will take up his new office on September 1 next, and is to receive a salary of $8,000 a year. A handsome residence will be immediately built for him on the University campus. The University has an annual income of a quarter of a million dollars. Dr. Dabny will, as president, also be at the head of the Medical College of Ohio and the Cincinnati Law School, these being respectively the medical and law departments of the University.

Gift to Jewish Hospital.—Mr. Joseph Joseph, a wealthy iron manufacturer, has given $15,000 to the Jewish Hospital of Cincinnati, to be used in building a new dormitory for nurses. Other supporters of the institution have donated $5,000 to be expended on the necessary furnishings for the dormitory. It is also proposed to build upon the grounds a power-house for supplying heat and light.

The Cincinnati Hospital.—The Board of Medical Advisers of the Cincinnati Hospital reorganized Tuesday, and the following officers were elected: *President*, Dr. A. B. Isham; *Vice-President*, Dr. Louis Schwab; *Secretary*, Dr. Byron Stanton. A resolution was passed commending Dr. C. R. Holmes, resigned, for his faithful service.

Obituary Notes.—Dr. CORNELIUS E. BILLINGTON died at his home in this city on January 8 at the age of sixty years. He was a graduate of the New York University Medical College in 1863. He served for a time in the Union Army during the Civil War, and at the close of the war began the practice of medicine in this city. He was a member of the New York Academy of Medicine and of the Medical Society of the County of New York. He was the author of a work on diphtheria, which was regarded as authoritative for many years.

Dr. MARGARET PRESTON BUCKMAN died in Trenton, N. J., on January 7, from scarlet fever contracted while caring for her own child. She was a graduate of the Woman's Medical College of Philadelphia.

Dr. GEORGE H. HACKENBURG died at his home in Austin, Tex., on January 8 at the age of eighty years. He was born in Union County, Pa., and was a graduate of the New York University Medical College. He practised medicine in this State for many years, but removed to Texas in 1873. He was credited with being the originator of the idea of the telephone, having published, in 1864, in *Godey's Ladies' Magazine* an article on the principles of the telephone, which were afterward practically applied.

Dr. STUART H. REED died of pneumonia at his home in Madison, N. J., on January 6. He was born in South Carolina in October, 1854, but passed his boyhood days in New York State. He was graduated in arts from Williams College in 1878, and in medicine from the College of Physicians and Surgeons in this city in 1881. He had practised in Madison since September, 1882. He was for a number of years health board physician of Chatham Township, and was an active member of the Morris County Medical Society.

Dr. JAMES FRANCIS FERGUSON died at Central Valley, N. Y., on January 7. He was born in New York City in October, 1839, and was graduated from the New York University Medical School in 1860 and from Bellevue Hospital Medical College in 1861. He served in the Union Army during the Civil War, was wounded in the first battle of Bull Run and was confined for a time in Libby Prison. After his release he entered the service again as major and surgeon of the One Hundred and Sixty-fifth New York Volunteers. He served with General Banks in Louisiana, was present at the battle of Plain Stores, and at the siege of Port Hudson was in charge of a field hospital. He was afterward Provost Surgeon in New Orleans and served in the campaigns in the Teche country, and was discharged at Franklin, La., in 1864. He was brevetted Lieutenant Colonel of New York Volunteers. His professional appointments were as follows: Attending surgeon Bellevue Hospital, Outdoor Department, 1870-71; visiting surgeon to the Blackwell's Island Hospital, 1872-92; visiting physician to the Hospital for Nervous Diseases, 1886-92, and consulting physician of the Charity (now City) Hospital, since 1892. He was a member of the Society of the Alumni of Bellevue

Hospital, Medical Society of the County of New York, New York Academy of Medicine, and the New York Neurological Society.

Dr. FRANK W. SHAW died in Brooklyn on January 8, at the age of thirty-eight years. He was born in Lockport, N. Y., and was graduated from the Medical Department of the New York University in 1885. After a term of service on the house staff of the Presbyterian Hospital he entered on the practice of his profession in Brooklyn. He was a member of the Kings County Medical Society and of the Hospital Graduates Club of this city, and was assistant attending physician to the Methodist Episcopal Hospital, Brooklyn.

Dr. EDWIN FREEMAN, a prominent eclectic physician of Cincinnati, died in that city on January 4 at the age of seventy years. He was born in Nova Scotia, and was graduated from the Eclectic Medical College of Cincinnati in 1856. Until the outbreak of the Civil War he was professor of anatomy in that school. He then entered the Union Army as surgeon and served through the war. Later he came to New York and helped to organize the Eclectic Medical College in this city. On returning to Cincinnati he resumed his professorship of anatomy, later taking the chair of surgery, which he held until compelled to retire on account of failing health.

Dr. J. H. VANTINE died at Catawissa, Pa., on January 3 at the age of sixty-eight years. He was a graduate of Jefferson Medical College in the class of 1858, and during the Civil War served as surgeon to the One Hundred and Thirtieth Pennsylvania Volunteers.

Dr. HENRY J. BOWERS died at Myerstown, Pa., of diabetes on December 31 at the age of sixty-two years. He was graduated from Jefferson Medical College in the class of 1862.

Dr. CHAS. G. FROWERT died in Philadelphia on January 9 at the age of fifty-four years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1874.

Stomach Lavage without the Tube.—N. R. Gordon believes that in catarrh of the stomach and in nearly all forms of dyspepsia, especially the atonic variety connected with dilatation, washing out the stomach is the most valuable treatment that can be used. Most forms of gastric indigestion are accompanied by dilatation of the stomach to a greater or less degree. The greater curve of the stomach is increased, forming a bag, which serves as a receptacle for the prolonged retention of a portion of its contents. The downward extension of the stomach is frequently increased from ten to twelve inches over the normal. Thus the stomach is not able to expel through the pylorus all of its contents without some artificial assistance. There is a continual residue of stomach contents, consisting of food and secretions, which remain to ferment and contaminate the fresh supply of ingesta. The writer gives the following method for washing out the stomach: Soon after rising in the morning the patient should sip a pint of warm water containing a little salt; he should then lie down on the back and turn from one side to the other rapidly from ten to fifteen times; then turn on the left side and draw up the knees slightly; then make a voluntary contraction of the diaphragm and recti muscles. Repeat this from ten to fifteen times with a few minutes' rest between every three or four contractions. Then turn to the right side, repeating the same operation. Rest on the right side from forty to sixty minutes, giving time for the entire stomach contents to pass out through the pylorus into the duodenum. Many cases of dyspepsia can be cured by this process. The diet must be simple, and the patient should never eat until he is hungry.—*The Alkaloidal Clinic.*

Correspondence.

CONSOLIDATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE NEW YORK STATE MEDICAL ASSOCIATION.

To the Medical Profession of the State of New York:

THE Sub-Committee of the Joint Committee on Conference presents the following plan of consolidation of the Medical Society of the State of New York and the New York State Medical Association for the information of the medical profession of this State.

The plan is the result of much labor, legal investigation, and careful thought and attention on the part of the committee; and the organization recommended for the consolidated corporation is one which is now in successful operation in thirty-two States of the United States. It is based upon the form of Government of the United States and care has been taken not to interfere in any way with the autonomy of county organizations, or with their property or other vested rights.

We respectively urge the members of the profession to promote by all proper means the passage by the Legislature of the proposed act prepared by counsel for the committee, authorizing the consolidation of the Medical Society of the State of New York and the New York State Medical Association. The proposed act will be introduced in the Assembly or Senate in due course, and, if passed, will authorize the consolidation upon terms to be agreed upon by the two corporations. The consolidated corporations will be known as the Medical Society of the State of New York.

Before the agreement for consolidation under the proposed act will become operative or effective for any purpose, it must be authorized or ratified by the vote of each corporation at an annual meeting, or else at a special meeting of each corporation called to vote upon the agreement, and it must also be approved by the county medical societies in affiliation with the Medical Society of the State of New York.

The agreement to be recommended by the committee for adoption in accordance with the terms of the act will contain provisions for giving effect to the following stipulations:

First: All assets and liabilities of the New York State Medical Association shall be transferred to and vested in and assumed by the Medical Society of the State of New York, at the time of consolidation.

Second: Expert accountants shall be employed to ascertain the assets and liabilities of each corporation, and their reports shall be submitted with the agreement for consolidation.

Third: All members of the New York State Medical Association in good standing at the time of consolidation shall be admitted to membership in the Medical Society of the State of New York.

Fourth: All members in good standing of the county medical societies now in affiliation with the Medical Society of the State of New York shall be admitted to membership in the Medical Society of the State of New York.

Fifth: All members in good standing of the New York State Medical Association shall be admitted to membership in the county medical societies for the counties in which they respectively reside.

Sixth: All members in good standing of the Medical Society of the State of New York shall be admitted to membership in the County Medical Societies for the counties in which they respectively reside.

Seventh: The plan of organization, constitution and by-laws of the New York State Medical Association, with such modifications as have been agreed upon by the Committee, shall be adopted as the plan of organization, constitution and by-laws of the Medical Society of the State of New York.

Eighth: The following proposition shall be submitted by referendum to the vote of the members of the consolidated corporation, namely:

The principles of medical ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public.

Ninth: The Medical Society of the State of New York will petition the Legislature for the passage of such further enabling Act as may be necessary, if any, to carry the consolidation agreement into effect.

"AN ACT

"TO AUTHORIZE THE CONSOLIDATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE NEW YORK STATE MEDICAL ASSOCIATION.

"*The People of the State of New York, represented in Senate and Assembly, do enact as follows:*

"SECTION 1. The Medical Society of the State of New York, incorporated by or pursuant to chapter one hundred and thirty-eight of the laws of eighteen hundred and six, entitled 'An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State,' and continued by chapter ninety-four of the revised laws of eighteen hundred and thirteen, passed April tenth, eighteen hundred and thirteen, entitled 'An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State and the New York State Medical Association, incorporated under chapter four hundred and fifty-two of the laws of nineteen hundred, may enter into an agreement for the consolidation of such corporations, setting forth the terms and conditions of the consolidation and the mode of carrying the same into effect.

"Each corporation, party to the agreement, may petition the Supreme Court for an order consolidating the corporations, setting forth in such petition the agreement for consolidation and a statement of all its property and liabilities and the amount and sources of its annual income. Before the presentation of the petition to the court, the agreement must be approved by a majority of the vote lawfully cast at an annual meeting of each corporation, separately, or at a meeting of each corporaton separately and specially called pursuant to its by-laws for that purpose, and a certificate of such approval, verified by the president and secretary of the meeting shall be annexed to that petition.

"On presentation of the petition, the certificate of approval and the consolidation agreement, and on such notice to interested parties as the court may prescribe, and after hearing such interested parties as desire to be heard, the court may make an order for the consolidation of the corporations on such terms and conditions as it may prescribe.

"When the order is made and duly entered, the corporations, parties to the agreement, shall be one corporation under the name 'Medical Society of the State of New York,' which shall not be deemed to be a new corporation, but to be a continuation of the Medical Society of the State of New York, incorporated in eighteen hundred and six. A certified copy of said order shall be filed in the office of the Secretary of State. All the property belonging to the corporations so consolidated shall vest in the said Medical Society of the State of New York, which shall have all the powers, rights, and privileges possessed by either corporation at or immediately prior to the consolidation, and which shall be subject to all of the liabilities of each corporation.

"SECTION 2. This Act shall take effect immediately."

Respectfully submitted,

A. JACOBI,
GEORGE RYERSON FOWLER,
E. ELIOT HARRIS.

A PLEA FOR UNIFICATION AND UNIFORM ORGANIZATION OF STATE AND COUNTY SOCIETIES.

To the Medical Profession of the State of New York:

AFTER correspondence on the subject with members of the Joint Conference Committee, and others, more especially on the society side, I have been requested, as chairman of the committee which has had this work in charge from its inception, to prepare for publication an explanation of the plan of organization for State and County societies which has been so generally adopted in the last two or three years. As the plan was prepared and is recommended for universal adoption, is already in satisfactory operation in thirty-two States and in over 1,500 counties, and is likely to be adopted in nearly all of the other States as soon as their annual meetings occur, as the subject is one of interest at this time to every member and well-wisher of our profession, and more especially as the preparation of the plan for general adoption makes my committee as responsible to you for anything wrong in it as though we were members of your County and State societies, it seems entirely proper that the request should be complied with, and an attempt will be made to place beyond question the truth of the following propositions:

1. That existing professional conditions and estrangements are useless and senseless, that they are hurtful almost beyond calculation to both the profession and the public welfare, and that they are remediable.

2. That the plan of organization is based upon our system of civil government, that it was prepared with much care and unselfishness, and that it contains nothing untried, experimental, or impracticable.

3. That the county society is not only the unit of the organization, but the source of all authority and power in both the State and national bodies through a representative delegate system, and it is also the only portal of entry to the entire society system.

4. That coincident membership has been an old and perfectly satisfactory method in many States, is essential to complete organization, and that it is just and right. It would be as unfair to permit a physician to become a member of his county society and enjoy all the benefits arising from the labors of the State society, as to permit one to become a citizen of Ithaca or Troy without becoming a citizen of the State of New York and bearing the burdens and responsibilities of the same.

5. That amendment of any part of the plan is purposely made easy and is controlled by delegates from, and responsible alone to, the county societies.

6. That the time has come for unification, and that, while union under a defective plan, which the joint body could modify and improve for the common good, would be far preferable to a continuation of existing conditions, the one now proposed has been found excellent and practical after full trial in other States, and, having been prepared away from New York contentions and controversies, it offers a basis for compromise honorable alike to both factions and to neutrals.

In order to establish these propositions clearly and satisfactorily, a brief history of this reorganization movement is necessary. From the very outset the magnitude of our task grew upon us. Although in name medical societies—city, district, State, and national—existed without number, and medical machinery and high-sounding official titles were provided sufficient for the civilized world, membership in most of them was small and little more than nominal, and, outside of a few States and localities, the profession was so torn with dissensions that it was in chronic disgrace in its own and the public estimation, and in a large measure robbed of its power, by legislation or otherwise, to help either itself or the public, for whose benefit it was supposed to exist. Into a profession already so overcrowded that there was less room and remuneration for the average man than for clerks and skilled laborers, commercial medical colleges were annually turning loose thousands of new graduates, many poorly equipped for intelligent modern practice, and all of them without an hour's training in professional conduct, business methods, the importance of society membership, in which all should have been drilled with the care due to subjects to become of so much importance as soon as they come to serve the public, and face the problem of earning an honorable livelihood.

As a result, largely, of such lack of training, we found that of the 120,000 registered physicians in this country, only about 30,000, one in four, had ever been members of any kind of society, local, State, or national. Most cities were little better organized than the country districts, a large submerged element being often found within an easy walk of imposing medical and post-graduate schools, libraries, and hospitals, who had long lost hope of advancement, looked upon their profession only as a doubtful means of support, while those in the higher ranks wrangled and slandered each other, and brought odium on all, and Christian science, and other forms of bald, naked quackery took the cream of a patronage which a united, self-respecting, and honored profession would have deserved and received.

It was soon found, however, that these conditions, deplorable alike to the profession and public, were not universal. In Alabama, for instance, under a model plan of organization and resulting united profession, with over 1,500 of the 1,700 physicians members of the county and State societies, medical opinion was sought for the guidance of law-makers, executives and courts, the profession was honored and independent, and quackery was unknown. Kentucky, striving for the same ends under less perfect methods, had had no itinerant or advertising doctor within her borders for ten years, and the profession was aspiring to its rightful place as a directing force in public affairs. In a dozen cities, also, usually of the lesser rank in population, under similar influences, harmony, coöperation, and measurable prosperity prevailed, and was increasing.

Inquiry soon demonstrated that the personnel of the profession was much the same everywhere, and the difference in the conditions found was apparently entirely due to difference in methods of organization. After all proper allowance for personal equation in rulers, governments are liberal or despotic as determined by their organic laws, and, probably quite as much as with a nation, the constitu-

tion and by-laws of a medical society will set the compass and shape the policy which will largely determine the future for both itself and its individual members.

Influenced by such belief and considerations, my committee began its work four years ago by grouping those provisions for State and local societies which had resulted in the most effective organizations, and with great care made our first draft of a constitution and by-laws for submission to, and discussion by, conferences of leading men in the various medical centers where there was a reasonable degree of harmony. Later, the improved draft was published in the medical press and in pamphlet form and given the widest possible publicity. As we were performing an important, unselfish, and gratuitous public service for the common good, advice and frank criticism were cordially asked from all, and these came freely and helpfully, especially from the better organized States and cities.

With such assistance, and in the light of such criticism, keeping always in mind that the plan should be democratic and conform to our methods of civil government, with local self-government by the county societies as the central idea, a simple but comprehensive system was gradually evolved, almost ideal in its outline and possibilities, which, after full trial under the most diverse professional conditions has proven entirely practical, being so flexible that it could be as easily adapted to the Cook County Medical Society at Chicago, with 1,800 members, as to sparsely settled counties in North Carolina or California with ten members. Under its operations in one year in Michigan the membership increased from 560 to 2,100; in Kentucky from 390 to 1,600, in Tennessee from 300 to over 1,000, in Missouri from 400 to 1,500, in Arkansas from 190 to 703, and in like proportion in every other State adopting it.

It is a thoroughly democratic and American plan, using those much-abused terms in their broadest and best sense. As has been said, the county society is made the broad foundation and source of authority for everything, as well as the portal of entry to both the State and national bodies. If a physician stands well enough at home to secure membership in his county society, he is eligible for membership and for any position of honor or trust in the State and national bodies, and, if he loses membership at home, subject to the right of appeal, he loses out everywhere.

The house of delegates, the legislative and business body of the State society, like the general assembly of a State, is composed of representatives from the county and district societies, and such delegates are freed from political influence so far as possible by making them ineligible for any of the offices within their gift, and they are responsible alone to the constituencies electing them. As they are in session but two or three days, in order to make the transaction of business possible, unlike senators and representatives, they sit as one body. This gives a body small enough for deliberative work, and yet gives county societies remote from the place of meeting, and all others, an equal and only an equal voice, in all business affairs, if only the delegates are in attendance.

Carrying out the same principle of local self-government, this house of delegates, made up directly from county and district societies, elects from the general membership the delegates which, in turn, compose the legislative body of the American Medical Association. As in the house of delegates of State societies, this being a small body, with its members carefully selected and made ineligible for any other position, with the terms of half the members expiring each year so as always to have men of experience in it, and which can remain in session, if necessary, after the general meeting adjourns, it was hoped to provide a body in which the interest of the profession and of scientific medicine might be considered and promoted in the broadest way.

The question of coincident membership in county and State societies is one which should require little explanation in New York. It has given satisfaction in the association, and has, of course, been under the observation of the society people. You have also had ample opportunity to observe the results of it for years in the neighboring states of New Jersey and Connecticut, where it has been in operation for years. It has been long the practice in Alabama, with the result that about 90 per cent. of the profession are permanent members, as well as in Massachusetts, Pennsylvania, and Indiana, and recently in a total of thirty-two States. It is only one feature of the work, but it is so important that any complete or systematic organization of the profession is impossible without it. Besides, the justice of it is beyond question. It would be as obviously unfair to permit one to join his county society and enjoy all the benefits of the State society, arising from its legislative, educational, and other expensive and responsible labors, without assisting in its support, as it would be to permit a man, if one could be found so foolish and selfish as to ask it, to become a citizen of Buffalo, Syracuse, or Rochester, and enjoy all the benefits and protection of the State government, without becoming a citizen of New York.

It is true that in nearly every State where this plan of organization has been proposed, as was natural and to be expected, academic and purely theoretical objections have been made to some feature of it, usually to the council, the house of delegates, or to coincident membership. Such objections have always been made in advance of a trial of them, and they have been confined almost entirely to States which have been practically without organization heretofore. Conditions in Iowa illustrate this point well. The county society at Dubuque, which has reorganized and applied for a charter within the last ten days, raised many such theoretical objections to the plan before they had tried it, while eighty-eight counties in the same State, organized under it, and realizing its practical benefits, are loud in praise of the very provisions to which their worthy neighbor at first objected. It is a source of much encouragement that this has been the experience of over 1,500 counties which have reorganized.

It would be pleasant to comment on each provision of the plan in detail if space permitted. Suffice it to say that it was intended only as the foundation and framework for a broad and comprehensive system to be recommended for universal adoption, that nothing was included except for what appeared the best of reasons, and that it is susceptible of infinite elaboration and improvement in detail as the profession of any State or county develops under the catholic and coöperative spirit which it inculcates, and which is so much to be desired.

Attention is called to the fact, also, that much contained in the by-laws, where a wide departure is made from the brevity and compactness of expression adhered to in the constitution, is suggestive and educational in character, much of which would not be necessary if such an organization as is contemplated was already in existence. We thought it as important, under existing conditions of discord and demoralization, to furnish incentives to this work, to give practical and detailed information as to how it was to be done, and to put the reasons for it all within the reach of all those whose duty it would be to discuss the subject and do the work as to furnish the framework of which, as the result of years of devoted labor, they were to make a complete edifice occupied by a united and harmonious, or at least a decently coöperative and self-respecting, profession. For many reasons, too, amendment to the plan is purposely made easy. If after trial in any State anything is found obsolete or impracticable, it can be easily eliminated or replaced by something better adapted to existing needs, by the house of delegates, subject to instructions from the county societies, at any regular meeting, after such amendment has lain upon the table for one day.

Unification in New York has been so long the dream and hope of its own profession, as well as of the entire country, that now, when this seems about to be realized, it may be that a majority of you will consider mere methods and details of organization important only in so far as they are likely to hasten or delay the union. In part, this view of the matter is both natural and correct. A cordial union under a defective plan, which could be modified and improved to meet the needs of the joint body, when there would be unity of purpose and interest for the common good, would certainly be far better than to perpetuate the two bodies, even with model organizations or both, with the strife, discord, and loss of public respect inseparable from such conditions anywhere.

Still, if it can be shown, as the writer believes will appear upon the most critical investigation of what is now proposed, that it furnishes ready to your hands a plan of organization to which you may build and add with confidence in the results, and which will at the same time hasten unification by furnishing a basis of compromise between factions so long divided that suspicion and jealousy have become so much mental habits that neither will be willing to accept what the other proposes, it should, and I am sure will, receive respectful consideration at your hands.

In the era of good feeling and enthusiasm which must follow unification under such a broad, liberal, and comprehensive plan, which would give an equal voice and power to the individual doctor in every county, organization should and would make rapid strides, and the possibilities opened up to your profession, and then to your people, would be almost beyond conception. In the face of such possibilities, standing upon the threshold of such accomplishments, petty prejudices and personal interests appear so insignificant that they should find no place in large minds.

Then, as New York would be in perfect alignment with her sister States, with proper education and effort, everything desirable would, in time, be brought within reach

of the united profession of the entire Union. The complex and difficult problems before the profession of this country incident to our unprecedented advance in population and civilization, and which must be solved by it, if they are to be solved, will tax its highest intelligence and energies at its best. Provision can then be made for continuous scientific research, and for systematic collective investigation into the causes and prevention of disease, upon the large, generous lines demanded by the vast interests involved. The vexed problem of medical education can then be taken up with confidence and justly and wisely solved. Reciprocity in licensure and membership between States can then be discussed from the standpoint of the common good and settled upon some equitable basis. Constructive statesmanship can be substituted for the narrow, time-serving political methods of the present in municipal, State, and national public health affairs, and our great profession, great even now in spite of its divisions, united, elevated, and ennobled, would come to occupy its rightful place as one of the greatest of modern forces for the guidance and protection of our people. It would be an honor, even to New York, to lead in a reform promising such results, and to set an example in complete organization, which less favored and weaker States would imitate with both pride and profit. First of all, leading to all, and above all, in the words of your victorious commander, greater in magnanimity even than in war, "Let us have peace." J. N. McCormack, M.D.

Chairman of the Committee on Organization of the American Medical Association.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CHRISTMAS RECESS—THE LEAGUE OF MERCY AND THE KING'S FUND—KING'S COLLEGE HOSPITAL—UTERINE FIBROIDS—THE HEART IN ABDOMINAL OPERATIONS—MEDICO-LEGAL SOCIETY—SUBSTITUTION: THE "TABLOID" JUDGMENT—BALLACHULISH SETTLEMENT—TYPHOID IN OYSTERS AND WATERCRESS—OBITUARY NOTES.

London, December 26, 1903.

This being Christmas week there is but little going on about medical matters except in the quiet way of private practice. Just as the boarding schools have closed for a vacation and the boys and girls returned home for a holiday, so the students in the medical schools are enjoying their Christmas recess, and the medical societies where practitioners meet and talk are silent for a brief period.

Still there are a few items of temporary interest to gather while we put aside the graver questions, until the new year opens, when most of us hope to return to work after as much relaxation as urgent duties shall have permitted.

The treasurer of the League of Mercy has paid £10,000 to King Edward's Hospital Fund. The League collects small contributions in shillings and pence. This year the amount so raised has largely increased from the seventy-eight districts where the collection is made—nearly 50 per cent. over last year's contributions. The object of the League is to afford the humblest residents to contribute their mites to the work of the hospitals.

The removal fund of King's College Hospital has been promised £10,000 by the trustees of the Lunz fund, with the intimation that when the new buildings are open a further sum may perhaps be contributed to maintain the "Annie Lunz ward." On the other hand the City Council of Westminster has resolved to oppose the bill for removal unless the interests in a charity founded in 1687 for the benefit of Westminster be properly safeguarded. For some years King's has received £600 annually from this charity.

At the Gynæcological Society Dr. B. Fenwick showed a uterus containing fibroids which he had removed from a patient who had suffered for six years, was quite blanched from the continual loss, wasted and exhausted. Her first cardiac sound at the apex was fairly good, clear and distinct, for which reason he operated. He stated that he was much guided by the state of the heart in deciding the question of operating for abdominal tumors. When the first sound is distinct and clear he said there was not much, if any, fatty degeneration of the walls of the ventricle—the one particular degeneration which is often associated with long-standing abdominal tumors and causes the sudden death that occurs in these cases. The patient recovered well, although numerous adhesions made the operation a very severe one, taking nearly one and one-half hours to carry out. The case, he thought, also illustrated the suffering and danger too many women undergo through the archaic superstition that their fibroids will disappear at the monopause.

Sir W. J. Collins presided at the Medico-Legal Society when he urged the importance of medical jurisprudence and hoped it would receive more attention. The society might with advantage pay attention to such subjects as coroner's law; secret remedies; the position of doctor's in reference to professional secrecy; and other residual topics which have been too long neglected by both lawyers and doctors. Mr. Troutbeck afterward read a paper on juries for inquests, in which he discussed their qualifications. He thought seven or nine jurymen a good number for these inquiries.

The question of substitution having occupied the High Court for a week in connection with the great "Tabloid" case, judgment was reserved and has now been given. Messrs. Burroughs, Welcome & Co. have won all along the line, and so completely established their exclusive right to the use of the word "Tabloid" as their trade mark. We shall probably, therefore, hear of no further infringement, and the judgment will tend to make all kinds of substitution too dangerous to indulge in.

The Ballachulish dispute, about which I wrote to you, has at last been settled by the managers giving way before the determination of the quarrymen. You will remember these men were determined to choose their own doctor and refused to recognize the right of the masters by any clause of the agreement to dismiss him. No one can say the desire to choose their doctor was not reasonable, and even if the masters had a legal right to select or dismiss, it seems surprising that they could not see that this was so and acquiesce in the retention of the doctor who had won the esteem of the men—particularly as the men paid him. It came at last to an acquiescence or a strike and, of course, the men won on such a point.

A recrudescence of the oyster scare is threatened. A seizure of one quantity led to an examination by Dr. Klein, who reported that the sample was distinctly sewage-polluted. The case was brought before the Lord Mayor and adjourned for further investigation by Dr. Klein. The danger of watercress, about which I lately wrote to you, has also been rendered more obvious and disquieting by a statement in the County Council by the chairman of the Health Committee that twelve acres devoted to the growth of this vegetable are in close proximity to an adjacent sewage effluent.

The death is announced of Col. Sir George Thomson, M.D., K.C.B., formerly of the Indian Medical Service. He had a distinguished career, his services including the Afghan war, the Chitral relief force, and the Tirah expedition. He had also been P. M. O. in the Lahore District. He graduated at Aberdeen in 1843, and received the K. C. B. on his retirement to England in 1898.

Dr. Theophilus Trend, formerly physician to the Royal Hants Infirmary, died on the 7th inst. after a brief illness. Earlier in his career he was surgeon-major of the Hampshire Volunteers. For the last ten years he has been a J. P. and an active member of the Southampton Bench.

Donald McLeod died on the 5th inst. at Hawick, where his jubilee of practice was celebrated by his numerous friends in 1899 and he was presented with a silver tea service and a purse of money. He was in his seventy-seventh year.

Dr. Langton Philip Mumby, Major Royal Army Medical Corps, died on the 1st inst. He took part in the Tochi expedition was mentioned in despatches and awarded the medal. During the campaign symptoms of his fatal illness began, and though he struggled on until peace, he then had to be invalided for it—tuberculosis of the bladder extending up to the kidney.

Is It Necessary to Continue in the Prophylactic Isolation of the "Carriers of Bacilli" in the Epidemics of Diphtheria.—C. M. F. Sinding-Larsen has for three years, as a result of his own personal experience, expressed his doubts as to the possibility of accomplishing, at least in general practice, prophylactic isolation of the "carriers of bacilli" (in latent cases) in the course of epidemics of diphtheria. Now for the first time he defines his ideas on this subject. He admits that the latent cases may be contagious, but he suggests as a substitute for isolation, prophylactic injections of serum as less expensive and less irksome, as well for physicians as for the public. His hospital experience with scrofulous children during an obstinate epidemic of diphtheria has demonstrated to his complete satisfaction that the bacteriological proof is extremely uncertain in the absence of clinical symptoms. He believes that the time during which many individuals, especially those who are very tuberculous, can retain in the throat the diphtheria bacilli is to a certain extent indefinite. In consequence he believes that isolation is impracticable.—*Norsk Magasin for Laegevidenskaben.*

CONCERNING THE LACRYMAL DILATOR.

To the Editor of the Medical Record:

Sir: In the Medical Record of December 19, 1903, Dr. J. Wilkinson Jervey of Greenville, S. C., describes the treatment of lacrymal obstruction by means of his dilator. No doubt the idea of using the instrument was original with the Doctor. I am sure, however, that this method of treatment is an old one—how old I cannot say. In the *Ophthalmic Review*, Vol. I (1882), page 363, in an abstract of an article written by Galezowski of Paris, which was published in *Recueil d'Ophthalmologie*, August, 1882, describing a new treatment of the lacrymal passages by a dilator. I will quote from the abstract: "The instrument employed is a dilator, the blades of which, when closed, form a smooth, round probe, equal in thickness to Bowman's No. 4. When the blades are together the handles are separated. The closed blades are passed into the duct like an ordinary probe. The handles are then pressed together, and the blades, in separating, produce an effect equal to that of Couper's largest probe; at the same moment the instrument is withdrawn." From this description, I should judge that Jervey's instrument is similar to that used by Galezowski over twenty years ago. Probably Galezowski was not the first ophthalmic surgeon to use the lacrymal dilator.

Acute Flexion of the Gall-bladder as a Cause of Biliary Colic: Its Relief by Operation.—A. T. Cabot reports two cases in which characteristic attacks of biliary colic seem to have been caused by the acute flexion of the gall-bladder at about its middle. In all such cases when there are adhesions it is difficult to recognize on the operating table the exact condition which is responsible for the colic. As a rule the operation is done between attacks, thus in many cases the mechanical obstruction or drag is not in action at the time of operation. It is probable when the stomach or colon is united to the gall-bladder or the gall ducts by adhesions, that the drag of these viscera is responsible for the distortion which causes the colic. This drag may be very much increased when these viscera are loaded, and may amount to but little when they are empty. The writer considers cholecystectomy as the better operation in these cases under discussion. He has had excellent success with this method of treatment.

The Boston Medical and Surgical Journal, Jan. 7, 1904.

On Some Questions Relative to Extrauterine Pregnancy, with Especial Reference to Tubal Abortion.—Malcolm Storer has operated upon seventeen cases of extrauterine pregnancy, and has diagnosed correctly quite a number more which were sent to others for operation. In several of his cases the correct diagnosis was not made until the abdomen was opened. In very few of these were even a majority of the classical symptoms present. But there were a large number of cases having most of the classical symptoms in which a laparotomy showed other conditions. According to the writer's opinion, the symptoms which seem of chief importance in tubal abortion are pain and anomalous escape of blood from the uterus. The pain is often accompanied by nausea without vomiting. As a rule more or less protracted metrorrhagia takes place. The further advanced an ectopic is, the easier is the diagnosis. Ectopic pregnancies are far more apt to occur in multipara after a protracted secondary sterility. This is not always strikingly so; 41 per cent. of the writer's cases were primiparæ. As to treatment, the writer first discusses the question of delay in operation when a case is seen immediately after rupture in collapse and acute and profound anæmia. The writer does not advocate the waiting policy, but prefers to operate at once. He also believes that a reasonably probable diagnosis of unruptured extrauterine pregnancy implies an immediate operation. In cases of tubal abortion, a month or so before the patient is seen, the mortality of the cases treated by operation is practically the same as that of the cases treated expectantly, but in the former the convalescence is far shorter. The writer prefers the abdominal route. He believes that there is great hope that an extrauterine pregnancy may be followed by a normal one.

Typhoid Fever in Children.—Adolf Baginsky gives as the chief diagnostic signs of typhoid fever, the general appearance of the patient, the characteristic remittent fever, gastric disturbance, diarrhœa, condition of the tongue, enlargement of the spleen, roseola, and the diazo-reaction. The differential diagnosis between typhoid fever and miliary tuberculosis is often difficult. In many cases we must wait for the appearance of meningitic symptoms, irregular pulse, vomiting, constipation, and finally general convulsions before we can be sure of the latter condition. Repeated blood examinations will undoubtedly greatly assist in differentiating pneumonia and typhoid fever. In pneumonia there is generally an increase of the leucocytes, while in typhoid fever they exist in diminished numbers. Frequent physical examination will reveal the pneumonic center in the lungs. The prognosis of typhoid fever of children is, as a rule, favorable. The writer has observed eighty-eight cases in the hospital, five of which died, a mortality of 5.6 per cent. In his private practice he has been more successful. The most insignificant and shortest forms of typhoid fever often occur in children, and are but a weak reflex of the typical illness. The prognosis of this disease depends very materially upon the treatment and the period at which it is begun. Moderate antipyretic treatment with a consideration of the complications improves very considerably the prognosis, undoubtedly. Proper diet and careful nourishment decide the prognosis in many cases. Pneumonia, parotitis, or other infectious disease, or even noma, as a complication seriously affect the prognosis. Even in the light epidemics of typhoid fever the strictest prophylaxis must be exercised. Children should be protected from the use of infected water and food, particularly milk. Everything coming in contact with the patient should be disinfected. The antipyretic method of treatment has the same importance for children as for adults. The two great groups of remedies are: (1) The bath and the cold pack. (2) The internal administration of antipyretics. Each case must be dealt with according to its individual needs. Children with typhoid fever cannot stand very cold baths. The younger the child, the more care must be taken in this regard. Children bear the cold pack very well. The permanent lukewarm bath, according to the method of Riers, is apparently to be recommended. Success in the treatment of typhoid fever depends largely upon the proper nursing of the patient. Bouillon, wine, yolk of egg with water and wine, milk, cornstarch preparations, plasmon and somatosa are among the foods that may be given. All solid food is forbidden. The organs of respiration require particular attention. Narcosis must sometimes be resorted to to quiet restlessness. During convalesence it is particularly important to watch carefully the digestive organs.

Journal of the American Medical Association, Jan. 9, 1904.

Shall We Operate on Deformed Septa in Cases of Atrophic Rhinitis?—K. W. Baldwin gives an affirmative answer to this question stating her views as follows: After a careful study of the cases and a few thorough cleansings, operate. Operate first on the sinuses of the roomy side if they are involved. As completely as possible, correct the septal deflections, removing only the thickenings necessary to bring the septum into the median line. Later smooth up the septum as the individual case may demand. The tissues have not the recuperative power of normal nasal tissues, and much care must be used in the operation, not only to remove as little tissue as possible to gain the desired correction, but to make no undue or unequal pressure, especially on the cartilages. Change the splint frequently and continue its use the shortest time possible. Never use a pin in an atrophic septum. A pin will of en cause perforation in twenty-four hours and, once formed, the conditions are not favorable to its closure. Stimulate all cut edges to secure an over, rather than an under, inflammatory reaction Excessive granulation tissue can easily be removed. With these precautions she is confident that operative interference will hasten the cure of atrophic cases.

Typhoid Fever: Some Unconsidered Hindrances in Its Prophylaxis.—J. S. Fulton calls for a more careful study of this disease. He is convinced that of all mortality changed in the South to malaria, half perhaps is really due to typhoid fever. The latter disease is far more common than has been generally supposed. It has at the present time and in this country, a heavier incidence on small communities and rural districts than on the larger cities. From a careful study of census statistics and mortality reports, Fulton is convinced that the typhoid reported in the United States is not more than 65 per cent. of that actually occurring. A very large majority of the deaths attributable to malaria is due to causes in which the latter malady does not even participate. The infection is more heavily seeded in smaller communities and the propagation is in general from the county to the town rather than in the opposite direction. Prophylaxis consists essentially in defence against excremental contamination and precisely as the barriers are more or less remote from the sources of infection, is the defence less or more effective. Fulton believes that to set up at the gates of a city, expensive works for the purification of the public water supply as a main defence against water-borne disease is literally a preposterous arrangement. It waives the choice of time,

place, and weapons, conceding all these advantages to the enemy. It assumes that the vices of rural insanitation are invincible, but they are not. If there is one direction in which, more than another, the political influence of great cities should be exerted, it is to bring rural districts and small communities under legal obligation to render strict account of deaths and the causes of death, and to take and give good heed to the preventable diseases at the time and place of their occurrence.

Medical News, January 9, 1904.

The Value of Climate in Genitourinary Tuberculosis.—W. H. Prioleau believes that as a general rule a moderate altitude, when it suits a case, is most desirable. When a patient regains his health at such an elevation he can return home with less likelihood of the disease reappearing. But if he regains his health at a very high altitude, it is questionable whether it is advisable for him ever to leave there. Climate is a most valuable adjunct to the treatment of genitourinary tuberculosis, but it cannot effect a cure by itself. Superalimentation most undoubtedly does harm in urinary tuberculosis. Instrumentation of the tuberculous genitourinary apparatus is seldom advisable.

Seasickness.—William F. Waugh likens the condition of seasickness to the state induced by snake venom—a paralysis of the abdominal vasomotors with accumulation of the blood in the viscera, and consequent anæmia elsewhere, especially in the brain. He advises the following treatment. To an adult is given atropine gr. $\frac{1}{1000}$ every ten minutes until slight dryness of the mouth is felt. The dose is then suspended, not to be repeated till the dryness begins to subside. Strychnine should be given in doses of gr. $\frac{1}{12}$ every ten minutes until the pulse has acquired normal tonicity, and after that, just often enough to sustain this effect. The mind should be kept diverted. Before the voyage, the alimentary canal should be cleared out. A salutary abstinence should be practised before and during the trip. The remedies here advised should be taken in a spoonful of hot water.

The Mortality of Appendicitis.—Frederic S. Dennis states that the mortality in appendicitis in all cases under medical treatment is about 16 per cent., with 30 per cent. of relapses. In diffuse suppurative peritonitis it is almost uniformly fatal. The mortality in appendicitis in all cases under surgical treatment is about 4 per cent., and with no relapses, and in diffuse suppurative peritonitis the mortality in the published statistics is from 31 per cent., the lowest, to 91 per cent., the highest. The mortality in the writer's eleven consecutive cases of diffuse suppurative peritonitis was zero. He believes from his study of all available recent statistics, that any case, after thirty-six hours, that is not improving in every way, should be operated upon at once. Fowler has demonstrated that with operation in forty-eight hours in 127 cases, 83 per cent. recovered. When the cases were left to the fourth day, 60 per cent. recovered; to the fifth and sixth day, 58 per cent.; to the seventh to eight day, 50 per cent.; to the ninth to tenth day, 33 per cent. The writer approves of allowing the simple catarrhal cases which are doing well after thirty-six hours to recover without immediate operation. They are classed as interval cases. The introduction of the interval operation offsets the tendency to indiscriminate operation. The writer believes that the mortality in appendicitis can be reduced only by a hearty, cordial coöperation of both physician and surgeon.

New York Medical Journal, January 9, 1904.

Radium: Induced Radioactivity and Its Therapeutical Possibilities.—S. G. Tracy finds that normal salt solution is one of the best media for the manifestation of induced radioactivity which may be tested by either the electroscope or a sensitized photographic plate. His method is thus described: Two hermetically sealed tubes of radium bromide are placed in the bottle of salt solution. One tube contains a small quantity of pure radium with the maximum radioactivity—1,800,000 the other, 10 milligrams of 950,000 radioactivity. The tubes remain in the solution for twenty-four hours, when they are removed and the solution is allowed to stand for twenty-four hours more. It is then found that the latter manifests considerable radioactivity, as is shown by skiagrams shown by the author. The experiment has been repeated a week later with the same solution and with the same result, thus showing that the radioactivity is not lost. But even though the emanations be lost, the "active matter" remains, and will continue to produce radiations for several hours afterward. The radioactivity of the normal salt solution may be stimulated by burning magnesium near it, or by exposing it to the spark from a Leyden jar or a static machine. Exposure to the ultraviolet rays will also stimulate it. Tracy states that this form of radioactivity possesses marked germicidal and autoseptic properties, and he suggests its employment in superficial malignant disease, skin affection, etc. The salt solution treated as above can be used internally, on dressings, as a spray, etc.

Some Observations on an Unusual Case of Scurvy.—The case is reported by J. Davidson, whose patient was a boy of seventeen years, whose symptoms were explainable on the theory of a multiple neuritis, recovery being sufficiently complete to leave no marked loss of muscular power, but leaving some evidences of muscular wasting and degenerative reaction. His symptoms included hæmoptysis and tendencies of nephritis and endocarditis, all of which were regarded by the author as of a scorbutic nature. Prompt recovery ensued upon the establishment of the usual autoscorbutic regimen. As differential points between the symptoms and those of spinal hemorrhage, the author mentions the following, suggesting a peripheral lesion: (1) The onset and development which were rather gradual; (2) the exact symmetry; (3) the exact and accurate limitation of palsy, atrophy, and particularly of sensory disturbance to distribution of ulnar nerve (all the other nerves involved having recovered, some entirely, some almost so); (4) the selection of the most terminal nerve branches to the exclusion of nerves nearer the center; (5) the recovery of median nerve and continuing palsy of ulnar nerve on the same side; (6) the absence of pupillary disturbance (and of bladder, rectum, and other spinal cord symptoms); (7) the absence of areas of sensory disturbance in strips along regions corresponding to spinal cord sections. Whether the multiple neuritis was caused by hemorrhages into the nerve sheaths or was of toxic origin cannot be positively stated.

American Medicine, January 9, 1904.

Tubism, the Lavage Habit.—C. D. Spivak describes the patient who has become addicted to the use of the stomach tube on all occasions. He states that not more than 20 per cent. of cases of gastric disturbances need lavage. When this treatment is indicated, two or three times a week is generally sufficient for all purposes. The writer uses the stomach tube in all gastropaths for purposes of gastric analysis, and finds that eighty will do well on a treatment of regulated diet, medicine, massage, physical culture, out-door life, and hydrotherapy. He concludes that lavage of the stomach is used by physicians without due discrimination. The stomach tube should never be allowed to be used by the patients themselves. To the many acquired vicious habits must now be added that of "tubism."

Observations on Uncinariasis.—Louis M. Warfield calls attention to a new species of parasite peculiar to our country, uncinaria americana. Whole communities in the South are infected. It is one of the commonest diseases, in that part of the country. It is the chief cause of anæmia in children especially, as they are the ones most liable to infection. Adults, if not too badly infected, seem to outgrow it, presumably through death of the worms. Ground-itch is intimately associated with uncinariasis, and infection most probably arises from contamination of the hands and later swallowing the embryos. Infection other than through the mouth is thought to be very improbable. While no adult worms were found in the cases described by the writer, the size of the eggs left no doubt that the infecting agent was unicaria americana. Prophylaxis rests with the country physicians, who should urge the building of latrines or privies that can be easily cleaned and disinfected, and which are closed below, so that barnyard fowls cannot get at the discharges, and so protected that rain cannot wash the discharges over the adjacent soil. Parents should then see that children use the privies, and do not defecate whenever they happen to be when they feel the desire. It is impossible to infect man with the uncinariaf of dogs or of other animals, so the problem of prophylaxis is simpler than it would otherwise be. Man is here his own worst enemy. This disease is the worst foe of labor that a community can have and a new era will dawn for the country districts in the South as soon as they are rid of this vampire.

Results of an Experimental Treatment of Epileptic Insanity.—J. W. Wherry gives his reasons for the treatment he has given in cases of epilepsy. He believes that epilepsy is a condition of autointoxication, producing a vasomotor spasm, from which the convulsion follows. The treatment was to be directed toward the vasomotor system instead of toward the brain. It was to be a combination of drugs, which would, if possible, prevent excessive vascular constriction and at the same time improve the general health. It was based upon the nitrites instead of upon the bromides, and its object was vasodilation rather than brain stupefaction. During this course of treatment no change was made in the diet of these patients, nor in their daily habits. Whatever benefits

were derived must have come from the treatment itself. The change in the patients has been remarkable. The quarrelsome and irritable disposition has practically been eliminated. With its exclusion the violent, vicious, and disorderly tendencies have disappeared. The decrease in the number of convulsions has been marked. Extending over a period of two years, there has been a reduction from an average of forty convulsions per month for each patient in May, 1901, to an average of three convulsions per month for each patient in April, 1903. The decrease in severity has also been marked. Only the most pronounced and confirmed epileptics were selected as illustrations. The writer started with the idea that the prime cause of epilepsy was a self-eliminated toxin, whose presence produced excessive constriction of the arterioles, and that the unconsciousness and the convulsion were the legitimate offspring of this unusual vascular spasm. The fundamental principles of the treatment are: A combination of vasodilating drugs with a saline cathartic and an alterative. The particular ingredients to be used in each case can be safely left to the judgment and discretion of the attending physician.

The Lancet, December 26, 1903.

On the Use of Pure Carbolic Acid in the Treatment of Smallpox.—J. T. Neech and J. F. Hodgson give their later experiences with this mode of treatment. Their cases number now 136, of which five died. The method consists essentially of applying the acid to the vesicles over a certain area of the body each day, commencing with the face and head until all vesicles have been treated. The applications are continued until the vesicles abort or dry up. Care must be taken to prevent the acid from running on to healthy skin. Carboluria was noted in only two cases, both belonging to the same family. The application of the acid caused very slight and transitory pain and relieved the intense irritation. The patients never complained or scratched themselves. The effect appeared to be local, the pustules rapidly shrivelled and scabbed, and the further development of the papules and vesicles was either prevented or, if not aborted, comparatively little discharge resulted. In fact, all the vesicles had formed into scabs in from five to ten days after treatment, according to the severity of the cases, and in from ten to eighteen days the scabs had fallen off, except, of course, those in the palms of the hands and the soles of the feet. The ulceration of the skin in the pustular stage was practically prevented, so that dermatitis with cutaneous and subcutaneous œdema was lessened, and the tendency to the formation of scars was not nearly so great. The offensive odor from the eruption was entirely absent and to a certain extent the application kept the patients clean. The absorption into the system of septic material from the pustules is either prevented altogether or is only very slight. This along with the lessening of the process of ulceration abolishes the secondary fever or renders it very mild. The temperature generally kept at a low level after the appearance of the pustular stage, and was never much above 102° F. even in confluent attacks in unvaccinated persons, and was normal long before it usually is in untreated cases. Delirium was very infrequent and the pulse was not markedly increased, as is usually the case when the pustular stage is reached. The risk of infection by aërial convection is also, we consider, much lessened, and we can discharge a patient with a greater feeling of safety a week or a fortnight before the usual time, as the treatment cuts short the disease to that extent at least. There was an entire absence of complications, such as multiple abscess, etc. The early removal of the scabs was effected by means of carbolic oil, bread poultices, and antiphlogistic applications which tended to prevent the formation of small superficial abscesses.

Deutsche medicinische Wochenschrift, December 24, 1903.

The Scarlatiniform Rashes Appearing after the Injection of Diphtheria Antitoxin.—Oberwinter, using a material comprising 200 serum injections, found that true serum rashes of exudative type occurred in only 2½ per cent. Owing to the prevalence of a scarlatina epidemic at the time of making the observations, considerable difficulty was experienced in determining the true nature of other much more numerous scarlatiniform rashes. It was found that those diffuse punctate rashes developing within three to five days after serum injection (or admission to the hospital) were to be regarded with the greatest suspicion, and that in most cases these revealed themselves as true scarlatina. The fact that the rash begins at the site of injection is not at all positive evidence in favor of a benign nature, for scarlatina may begin in the same way. The author furthermore believes that true double infections with scarlatina and diphtheria occur, and that many of the scarlatiniform eruptions occurring in hospital diphtheria cases are due to such double infection outside.

Arsenic Habituation.—Hausmann was led to make some observations on the action of arsenic on animals, particularly to test the immunity to the drug supposed to be produced on long taking. His results are somewhat at variance with the time-honored beliefs, for he found that in cases on record doses much larger than those usually considered fatal had been taken by ordinary individuals without causing death, and that even the famed arsenic eaters of the Steiermark do not exhibit a very appreciable immunity, though it undoubtedly does exist to some degree. It is not certain, however, that they can take ordinarily fatal doses with bad results. The author used chickens as experiment animals and found that with them as with man, individual powers of resistance played a large part. It was possible in selected chickens to produce a slight degree of immunity, about equivalent perhaps to that of the Steiermark *habitués*. The ill results supposed to follow the sudden omission of the drug in those accustomed to it could not be observed in the experiment animals, and it is probable that when arsenic is taken for long periods therapeutically, suddenly stopping it simply allows the organism to relapse quickly to the condition for which the drug was first given.

Berliner klinische Wochenschrift, December 21, 1903.

The Acoustic Transformation of the Pulse.—Sommer has succeeded in producing an apparatus by which the beat of of the pulse is transformed into a sound, the different qualities of which indicate the nature of the pulse curve. The principle is that of causing the fluctuations of the arterial wall to lengthen and shorten the reed of a musical pipe which is actuated by a continuous blast of air and gives a steady note which is modified by the impulse of the vessel wall. In this way a very delicate method of observation is produced which has certain advantages over the ordinary sphygmograph. Its principle point of superiority lies in the fact that it can easily be used during long periods of time, so that in functional cases, for example, when irregularities and intermittences occur only with considerable normal intervals, protracted observations are possible, while the kymographic record is limited by the shortness of the piece of smoked paper which must be used. The method is also said to give more accurate conceptions of the nature of each individual contraction. Permanent records are readily made by using a phonograph in conjunction with the author's instrument.

Discharge of Bones Following Fetal Putrefaction after Missed Abortion.—Rosenkranz publishes a case differing, he says, from all others in the literature in the fact that the fetal maceration took place in the short space of nineteen days and that the symptoms produced were very slight. The patient was a xi-para, who last menstruated on February 6. On June 1 liquor amnii was discharged and the patient was confined to bed for fourteen days with a slight temperature. There was moderate bloody discharge and the size of the uterus diminished rapidly; the cervix was not dilated. At a vaginal examination on June 19, two small bodies were found in the vagina and proved to be a carpal bone and a rib. During the next two weeks a number of other bones were discharged in the same way without any dilation of the cervix. On July 5 a moderate flowing took place and the cervix was found slightly dilated. The cervix and vagina were packed and on July 7 the remaining bones and the placenta were removed manually. The operation was accompanied by an intense odor of putrefaction. The number of bones removed was thirty-two, and all of them were completely denuded of soft parts. The patient made an uncomplicated recovery.

Berliner klinische Wochenschrift, December 28, 1903.

Tuberculosis and Pregnancy.—Hahn says that the view that pregnancy exerts a beneficial effect on tuberculous patients, or at least is well borne by them has been exploded. Pregnancy must be regarded as a serious complication of the disease and gains in gravity the oftener it occurs in the same patient. The prevention of conception in tuberculous patients is therefore a vital point in the combat against the disease. If pregnancy has taken place, the patient should be kept under close observation, and if her condition is not satisfactory, an abortion should be induced after consultation with a colleague. In the later months, premature labor has no advantages over the normal termination of the pregnancy, and a healthy child may be born which, under hygienic conditions, may grow up without contracting the disease. Pregnancy is always a drain on the system, andin tuberculous patients requires especial care, so that the societies for the prevention of the disease should devote much attention to such women of the poorer classes. The plan advocated by Maragliano

and Hamburger of invariably interrupting the pregnancy in tuberculous women cannot be carried out.

Syphilis Inoculations in the Anthropoid Ape.—Lassar, actuated by the results of Metschnikoff and Roux, successfully repeated their inoculation of a chimpanzee with syphilitic virus. The animal was a vigorous male four to five years old. The patient from whom the virus was obtained was a young man who had contracted the disease through the use of infected tatooing needles, and the material used was taken from the primary lesion on his arm. He also undertook the care of the animal after the infection, a matter of some importance, since, if the experiment proved successful, any injury inflicted by the chimpanzee on his healthy attendants would be likely to have serious consequences. Bits of tissue and secretion from the patient's chancre were placed in pockets and punctures made under the skin of the forehead, the ears, and in the mucous membrane of the mouth. These various spots healed promptly and without reaction, and only two showed any later change. These were above the eyebrows, and on the fourteenth day began to show induration, which subsequently assumed the typical appearance of the lumen chancre. Still more important as evidence of infection is the fact that other lesions developed in the palms of the hands, on the soles of the feet, and about the anus. Similar efflorescences appeared on the arms, the forehead, and on the scalp, which gradually lost its hair. Microscopical sections also contribute to the view that the formerly accepted dictum that syphilis is non-transmissible to animals is erroneous and that the anthropoid apes are susceptible to the disease.

The Indications for Splenectomy.—Jordan says that 400 cases of extirpation of the spleen are now on record, and that it is an established fact that the loss of the organ entails no injury to the individual. The technique of the operation has been developed so that now it is proper to undertake it even on purely relative indications. Rupture of the spleen is an absolute indication for the operation, and thirty successful cases are recorded. In splenic cysts the older method of incision and drainage must still be considered; though eight cases have been treated by excision without a death, and of seventeen treated in this way for echinococcus cyst only two ended fatally. Sarcomatous growths can be temporarily checked by this measure and one case of permanent cure is recorded. Every effort to remove the leukæmic spleen has ended fatally and the pseudo-leukæmias also do not promise much in this direction. The malarial spleen may be considered operable as as well as cases of simple chronic hyperplasia without discoverable etiology. In ten recorded cases of the latter 100 per cent. of cure were effected. Fourteen cures have followed seventeen operations for Banti's disease. If a wandering spleen appears normal in itself, splenopexy should be done, if, as is usually the case, it is enlarged excision is indicated, particularly as the long pedicle renders the operation easy and safe. Seven extirpations for necrosis and perisplenitic suppuration have resulted successfully. The author has performed the operation seven times with one death.

Münchener medicinische Wochenschrift, December 22, 1903.

Tabes Juvenilis and Hereditary Syphilis.—Hartmann describes the case of a girl of twenty who had been suffering from spasmodic facial pain since her thirteenth year. At the age of seventeen she suffered a severe exacerbation of these pains so that she was confined to bed for eight weeks and at the same time she lost her sight almost completely. Subsequently vision improved somewhat, so that she could do coarse work. At the age of nineteen she had a premature labor at the seventh month, and during the nine months that have elapsed since then menstruation has not returned. The facial pains had become so severe that morphine was required to control them. The physical examination was negative except for marked flushing and heat of the face, which was the seat of intense neuralgic pains, though not tender to pressure; and the presence of well-marked Westphal's and Romberg's signs. The optic disk was atrophic on each side. The author concludes that this is one of the unusual early cases of tabes, probably due to hereditary syphilis, as there was a strong suspicion of maternal infection. An unusual feature is the prolonged stage of pain, localized in the face, which is rarely involved in tabes, without the development of parasthesia or atoxia. Nothing was accomplished by syphilitic or other treatment.

A Contribution to the Premature Separation of the Normally Situated Placenta.—Schickele has observed ten cases of this rare complication and gives their histories and treatment. In five the hemorrhage occurred suddenly without warning, sometimes before, sometimes at, and sometimes several hours after the onset of the labor pains. In the others the bleeding was more or less gradual and intermittent. It is the author's view that an internal hemorrhage gradually accumulating and finally bursting through the cervix, is the beginning of all cases, and that a certain amount of damming back always occurs, so that the hemorrhage is never purely internal or purely external. The number of previous pregnancies has no obvious relation to the production of the lesion. Variations in the manner and rapidity with which the placental separation takes place give rise to the different types of the complication observed, but the separation is always more or less gradual. It is a mistake to make the diagnosis of premature separation only when the placenta appears immediately after the child. The treatment must be adapted to the special indications of each case, and consists in emptying the uterus as rapidly and with as little injury as possible. The metreurynter forms the best measure for this purpose and the Bossi dilator is not advised. When the child is dead, as it often is, perforation and extraction are indicated; if it is in good condition and the uterus not so tense through accumulated blood in its interior as to make the procedure too dangerous, version affords a rapid method of completing the dilation and extracting.

The Organism of Actinomycosis in Man.—Doepke draws the following conclusions from his study of growths obtained from actinomycotic infections in man: The actinomyces fungus grows on all media, but best on glycerin agar at body temperature. At room temperature growth is less vigorous; the organism is both aërobic and anaërobic. The colonies are superficial, the size of a millet seed, elevated, yellowish, with a depressed darker colored center and radiab striations which show best on gelatin. Gelatin is slowly liquefied, bouillon is made cloudy, with a slight precipitate but no pellicle. To exclude possible contaminations, cultures should be made from the granules themselves and not from pus. The course of development of the organism from these granules to the fully developed rods is by a process of lengthening of the granules, which next subdivide and then grow out to form filaments. After two to three days these show branching and finally break up into rods. The fungus temporarily loses the property of staining with gram in the stage of filament formation, but regains it in the branched forms and the rods. Club-shaped forms with radial arrangement were observed in young cultures and stained with gram. Clubs obtained from fresh pus differed from those in artificial cultures through a straightened and more slender form, and in the fact that they are joined to the end of the filaments in a cap-like manner. They furthermore are negative to gram. The clubs from artificial cultures of human actinomycosis have the same form, method of junction with the filaments and reaction to gram as the clubs obtained from pus of bovine actinomycosis. Old cultures form crystals of carbonates and phosphates, which are deposited as a sediment in bouillon and are found on the surface of sugar colonies. In gelatin they are either in the sediment or just below the floating colonies. The larger mulberry-shaped calcareous masses sometimes found in old gelatin cultures contain the same salts, but have active germs in their interior. The organism has been detected in carious teeth, and this emphasizes the necessity of asepsis by dentists.

French and Italian Journals.

Cysts of the Thyroid Gland.—M. Tillaux reports two cases of tumors developed in this gland, and about the size of a hen's egg. No interference with deglutition, and no dyspnœa was developed, neither was there any sign of Basedow's disease. The tumors were not a part of the thyroid gland, but could be removed without affecting its integrity—they were, in fact, cysts of the thyroid. These inoffensive growths, by their mere presence, often torment the patients to such an extent that they become melancholic, and sometimes even develope suicidal tendencies. Their removal is easy and harmless.—*Journal des Praticiens*, November 28, 1903.

The Communicability of Cancer.—M. Isch-Wall has collected a number of instances which seem to point to the contagiosum of cancer. Some of them are the following: Three friends often met and went fishing in a boat. One of them contracted cancer of the tongue, but continued to go fishing, frequently expectorating into the boat. He finally died. In the following two years both of his companions died of cancer of the stomach. A mother and daughter sleep in the same bed. The mother has a cancer of the breast, and the daughter has also developed one. Four persons in one family, living together in the country, died of cancer—in three, the cancer was situated in the pylorus, in one in the liver. One of the writer's patients had leucocythæmia, with lymphosarcoma of the neck. A few years after his death, his wife died of abdominal cancer, which appeared to have started in the intestines.—*Journal de Médecine de Paris*, November 29, 1903.

Opotherapy.—In a discussion of the subject, Mr. Cassaët spoke of having used renal medication in a desperate case of renal suppuration following lithiasis. The patient had been practically given up by her physician. The urine was purulent, the kidneys were enlarged, and the patient had passed a large number of calculi. The author gave her raw kidneys to eat every day without interruption, for five or six months, without the slightest symptom of intoxication being observed. Fifteen days after treatment was begun, the urine was clear, and the patient eventually made an excellent recovery. While under treatment, she ate kidneys only, and could not tolerate any other meat.—*Gazette Hebdomadaire des Sciences Médicales*, November 29, 1903.

General Subcutaneous Emphysema.—Aldo Tozzi describes the case of girl of nine years who was suddenly affected with laryngospasm and severe coughing. The diagnosis was difficult, no cause for the attack being discoverable. Santonin and calomel caused the evacuation of many lumbricoids. The following day the child was in a state of prostration so extreme that a fatal termination was looked for at any minute. This condition improved, to be succeeded by an extraordinary enlargement of the neck, owing to air in the subcutaneous tissues. This swelling gradually extended to the chest and arms; the face, the whole body, in fact, down to the feet were enormously distended, and the condition lasted for days. The parents, convinced that the child was dying, would allow of no interference. By degrees, however, the emphysema disappeared, the heart became stronger, the cough vanished, and in a month the child was entirely restored to health.—*La Riforma Medica*, November 25, 1903.

The Treatment of Cancer with the Serum of Adamkiewicz.—M. Katscher of Budapest reports a number of cases successfully treated with this substance. His wife had had two operations for mammary cancer, and had lost the use of one eye from cancer, beside having metastases at the articulations of the lips, and in the ribs. In July and August she was given eight hypodermic injections of cancer serum, which resulted in the disappearance of the metastases and of the disease in the eye. Visual power increased. In November five more injections were made, with further increase of visual power, and gradual but total disappearance of all ravages due to cancer. In another case, the wife of a professor in the University of Bucharest, had suffered from relapses after operation, and had been given up by all her physicians; after six weeks of treatment with the serum of Adamkiewicz, she was cured, and for more than a year has remained in perfect health. Several other cases are described, and the author expresses his belief in the remedy.—*Journal de Médecine et de Chirurgie*, November 25, 1903.

The Effects of Seaside Treatment on the Nervous System.—Maurice Mendelssohn states that the immediate effect of this treatment on man or animals, both sick and well, has no direct bearing on the general condition and does not alter the reflex excitability of the nervous system; but that the change in the excitability of the nerves is a secondary result. This treatment stimulates metabolism and causes a peripheral stimulation which acts reflexly on all parts of the nervous system, fulfilling the two fundamental requirements in all nervous affections, namely, improvement of the nutrition and the regulation of nervous excitability. The treatment exercises not only a tonic, but also a sedative, influence. The symptoms of nervous excitability which some patients show at the commencement of the treatment are of psychical origin. The seaside treatment is indicated in most nervous affections, especially in those which cause poor nutrition, when a tonic effect is desired, and in all nervous affections requiring sedatives; but is contraindicated in convulsive or paralytic conditions. This treatment deserves a high position as the most effective of all in nervous diseases.—*Bulletin Général de Thérapeutique*, December, 1903.

Cerebrospinal Meningitis from the Staphylococcus in Two Typhoid-fever Patients (Possible Contagion).—Émile Sergent and Henri Lemaire report these two interesting cases. They believe that the cerebrospinal meningitis which occurred as a complication in these two typhoid patients was due to the staphylococcus—the staphylococcus citreus. It might be suggested that the microorganism isolated from the cerebrospinal fluid was not the chief cause of the meningeal lesion, but that it developed only after the disappearance of another microbe, which had been the true pathogenic agent (diplococcus of Weichselbaum, bacillus of Eberth). This is indeed possible, but it is nevertheless true that the staphylococcus appeared in these cases to be the chief agent of the terminal accidents, since it was obtained in pure culture not only from the cerebrospinal fluid but also from an abscess of the lung. Besides this, it was noted in two patients who lay side by side. This authorizes the hypothesis of contagion. These are not isolated observations. In the epidemic of 1898–99 four cases of meningitis with a pure staphylococcus were reported. One of the cases had developed in the course of typhoid fever.—*Archives Générales de Médecine*, December 8, 1903.

Two Cases of Placental Retention after Abortion, One of Which Was Treated by Antistreptococcic Serum.—Thirion says that the treatment of troubles consecutive to abortion, when the membranes have not been expelled has given rise to numerous discussions. He makes this report, not with the idea of over-emphasizing the importance of his observations, but in order to give the results of his experience. The more important case was that of a girl of seventeen years. There was nothing of importance in either personal or family history. She had not menstruated within the last month and believed herself pregnant. She had had a severe hemorrhage. This was followed by fever and she was brought to the hospital for treatment. She presented the symptoms of infection. Antiseptic injections were given and curettage was performed. After this, artificial serum, 750 grams, were ordered. The serum was repeated on the morning of the next day; as the condition was not improved in the evening, 20 c.c. of antistreptococcic serum were given. The general condition of the patient was unfavorable. She was covered with profuse perspiration. This treatment was continued for several days. The patient made a rapid recovery. About two weeks after coming to the hospital examination showed that the uterus was small and very movable and the cul-de-sac free and not painful. The writer believes that this case is worth recording.—*Journal des Sciences Médicales de Lille*, December 5, 1903.

Tumors of the Bladder.—Guyon describes the course of symptoms which are often noted in a patient suffering from tumor of the bladder. Blood is urinated, although at first the hæmaturia is not very extreme. There is neither tenesmus nor pain. When the hæmaturia ceases, and it sometimes stops spontaneously, the urine becomes limpid again. It does not contain pus. Just as the physician and patient begin to think that they have suffered from false alarm, the hæmaturia begins again. Every time this symptom recurs it becomes more and more severe. The diagnosis is not always easy. Sometimes a large kidney is observed, and it seems natural to attribute the bleeding to this phenomenon, but the kidney begins to diminish in size, and it is seen that there is only renal distention, not a renal tumor. A bloody clot compressing the opening of the ureter into the bladder prevents the urine from passing off—consequently the renal distention. The writer then describes a case which had come under his observation, the symptoms of which were about like those above. The patient, a man of sixty years, was brought to the hospital. He had first, about a year before, when in perfect health, observed a little hæmaturia. There was no pain, and after the bleeding stopped, the urine became perfectly clear. At the time he entered the hospital considerable blood was passed in the urine. Careful examination revealed a pediculated tumor of the bladder. The tumor was benign in appearance. The writer declares his intention of removing it.—*Journal des Praticiens*, December 12, 1903.

Experiments on Obliterating Fallopian Tubes.—I. Rousse has found that a ligature carefully applied, or, still better, a section of the tube and broad ligament between two ligatures, is sufficient to obliterate a normal tube. The rare failures which have been published can easily be explained by errors in technique (too thick a pedicle or too loose a ligature) or alterations of the tissues. During the last year he performed one or other of these operations on six women with positive results. He recommends the section of the tube and part of the broad ligament between two ligatures in cases in which sterility is desirable because of an operation on the peritoneum. Either method is rapid and has no special objection, but troublesome adhesions or cystic degeneration of the organs sometimes take place. For these reasons the operation should not be done without sufficient cause. If obliteration of the tubes following certain operations (cæsarean section in marked pelvic deformity, ventral fixation in exhausted women, or the many children, abdominal operations in tuberculous women, cardiac disease, etc.) are considered legitimate, he is absolutely averse to all procedures for the sole purpose of rendering thoughtless when carried to an unwarrantable length, and they are dangers, because they expose the woman to an abdominal operation. On the other hand, they would reduce the number of medical abortions, not to mention the criminal ones. But this slight advantage is far from being counterbalanced by the greater dangers. Medical abortion has no more risk. Pregnancy itself can be averted with almost absolute certainty by entirely harmless means.—*Annales de Gynécologie et d'Obstetrique*, December, 1903.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 17, 1903.

ANDREW H. SMITH, M.D., PRESIDENT.

THE scientific program was in charge of the Section on Genito-urinary Diseases.

Operative Relief of Symptoms Due to Senile Hypertrophy of the Prostate.—Dr. PAUL THORNDIKE of Boston read this paper. He said that the catheter was useful up to a certain point; after that its use became unnecessary abuse. There was a class of prostatic patients in whom the obstruction had reached a point at which it became necessary to empty the bladder one or more times a day, and yet it was positively impossible to establish a proper routine use of the catheter. Another class of patients was absolutely unwilling to enter upon catheter life. Both of these classes should offer very favorable opportunities for operation. There remained, however, a very large class of cases, many of them, obviously enough, subjects for operative measures, and all of them easily made comfortable for the time being by the routine use of the catheter. If such patients were properly supervised and cared for up to the time when the urethra and bladder had acclimatized themselves to the new conditions of catheter life, many of them would go through their lives with a sufficient degree of comfort and an ever-decreasing risk to the integrity of the bladder and urethra. When such conditions could be secured, the catheter became a proper means of palliation; but when, for any reason, these conditions were unattainable, one reached that certain point at which the use of the catheter ended and its abuse began. That was the moment when operative relief should be sought, and it should be given at once, and not after months of a struggle carried on at the expense of pain, deterioration of the affected organs, and a material reduction in the chances of a favorable outcome.

During the past fifteen years much progress had been made, and much valuable experience had accumulated. Prostatectomy, from being a slow, bloody, and inaccurate procedure, carried out by the aid of cumbrous instruments and, for the most part, in the dark, had come to be a quick and accurate operation. These technical improvements in the operation had been marked enough to lessen materially the mortality of the procedure, and yet surgeons had been so engrossed with the technique of the operation that cases for operation had been chosen many times with a lamentable lack of discrimination, with the result that they were, at the present moment, quite unprepared to state just what was the real danger of such radical operation in properly selected cases. The real problem at the present time was in the selection of the proper case rather than of this or that method of operating. Certainly, few elderly men were good operative risks. Prostatectomy no longer offered the former 15 or 20 per cent. of mortality which it did a few years ago, but it was, and always must be, a serious and dangerous procedure, and one to be offered only to patients who were fair surgical risks. There were prostatics whose obstructive symptoms developed at so early an age that operation became a necessity while they were still comparatively vigorous men in good physical condition. There were others, older men, who, in spite of advancing years, maintained the physical characteristics of men much younger than themselves. These were the cases for prostatectomy, and while it was very difficult to describe accurately just what cases came into this class, and while it was certainly impossible to take the age of the patient as a guide to this classification, the decision would be well enough reached in the individual case provided the surgeon always realized that he had another alternative, provided he did not wish to assume the risks of the radical operation. Prostatectomy should always be the method of choice when possible, because it was really the only operation which offered the prostatic a cure. There was a class of cases in which unjustifiable risks were taken simply because of the need for a general anæsthetic. Whatever might be the scope or degree of the Bottini operation, it was certainly a far safer procedure than the more radical operations. Personally, he had been formerly very skeptical as to its usefulness, but he had come to the conclusion that it had a sphere of usefulness in certain patients, demanding relief, who were not good surgical risks. The operation required no general anæsthetic, and convalescence was exceedingly rapid. While its results were less certain than those of prostatectomy, it offered the patient a prospect of being able to do without a catheter.

Best Radical Operation for Senile Hypertrophy of the Prostate Gland.—Dr. ORVILLE HORWITZ of Philadelphia presented a paper on this subject, based upon a study of 141 radical operations. The surgical world, he said, was of the opinion that the danger began as soon as it became necessary to resort to the catheter. He would urge the importance of having a surgeon in attendance as soon as it became necessary to resort to the catheter. One cause for the diversity of opinion among surgeons regarding the proper method of dealing with prostatic cases was the attempt to apply the same method of treatment to all cases. The fact was that every case was a law unto itself, and the method of treatment must depend upon a careful consideration of all the features of the case.

The Bottini Operation.—Of all the methods that had been suggested, but two had stood the test of experience, the so-called Bottini operation and prostatectomy. He had previously tabulated the results of the Bottini operation, viz., 896 operations done by 48 operators, with 84.3 per cent. cured or improved, and 10 unimproved, and with a mortality of 5.7 per cent. In his opinion, it would always be regarded as a valuable surgical procedure, which, in certain cases, was capable of giving relief without special danger to life. The genitourinary surgeon could no longer afford to treat this operation with contempt. His own personal experience with the operation comprised 93 cases. Out of this number, 3 died. All of them were old men. Two died of uræmia and one of sepsis. He had been able to follow 81 cases for a sufficient length of time to obtain some knowledge of the ultimate results. There were 22 operations done in persons between 52 and 63 years of age, and in whom catheter life had already existed for some time. Of the patients operated upon between the ages of 52 and 76, all obtained symptomatic cures. As a rule, the prostatic obstruction was due to a fibrous enlargement. There were 15 cases operated on between the ages of 61 and 81, all patients who had been using the catheter for many years, and who were suffering at the time from cystitis.

Prostatectomy.—No routine method was applicable to all forms of prostatic hypertrophy. His own experience with prostatectomy embraced 50 operations. Nine of the operations were done by the suprapubic incision, and of this number, 2 died. Of 34 complete perineal prostatectomies, 6 cases were lost sight of. Of the 21 remaining cases, 16 were cured, 4 were markedly benefited, and 1 was not improved. Perineal prostatectomy was evidently of great surgical value, and was the most satisfactory method of reaching the gland. The operation could be done rapidly, with little hemorrhage and little or no shock. The mortality ranged between 5 and 25 per cent., the usual estimate being 15 to 18 per cent. At the present time, in the hands of the experienced surgeon, the mortality, in selected cases, should not be over 5 to 7 per cent. In 90 per cent. of the cases the prostate could be reached by the median perineal incision. From the 145 operations, the following deductions were made: A routine method was not applicable to the treatment of prostatic hypertrophy. The dangers attendant upon daily catheterism were greater than those attendant upon prompt operation at the time when it became necessary

to resort to the daily use of the catheter. The Bottini operation was applicable to a large percentage of cases, and, in properly selected cases, would prove to be the best and safest method of relieving the obstruction. A complete prostatectomy was justified if performed early, before the individual was broken down in health and secondary complications had supervened. The recovery was usually rapid under such circumstances. A complete prostatectomy in old people, who were feeble and presented complications, yielded a grave prognosis, the mortality ranging between 15 and 18 per cent. In 90 per cent. of all cases the gland could be readily removed by means of a median perineal incision. A suprapubic prostatectomy was safer if combined with perineal drainage. The perineal prostatectomy was suitable in those cases in which the enlargement of the lateral lobes tended to progress toward the rectum, obstruct the urethra, or project backward into the bladder.

Dr. L. Bolton Bangs opened the general discussion of these papers. He said that his own view of this subject had been admirably stated by Dr. Thorndike. A broad discrimination must be made between hospital patients and the well-to-do intelligent private patients. In the former class, the primary retention should be the indication for radical treatment. It was not so difficult to choose the operation as to decide when and upon whom to operate. Primary retention was not a sufficient indication for the treatment of the individual. The patient should, of course, be kept under the supervision of the family physician or of a surgeon in order that the golden moment might not be lost when operation could be done with the best results. It should also be remembered that every man who had frequent nocturnal urination and some residual urine was not necessarily a victim of a serious and progressive enlargement of the prostate. He had had some experience with prostatectomy and with the Bottini operation, and he was inclined to think that prostatectomy was the operation of choice in properly selected cases. Nevertheless he would admit that the Bottini operation was applicable to a certain class of cases, but he could not, at the present moment, accurately define the cases in which it should be used. In some cases it would give a great deal of relief, and in others, a positive cure, with a minimum of risk. He thought the Bottini operation required a little more skill than the performance of prostatectomy, because the latter operation was within one's sight or feeling. The Bottini operation required a certain degree of actual experience as well as dexterity to do it satisfactorily. The speaker said he did not think enough stress had been laid upon the ultimate effects of operation. He had known some who, for the rest of their lives, had had to have sounds passed, or had suffered from more or less incontinence, or who had been annoyed by the absolute loss of the sexual function. There was also at times a certain amount of psychic change. He had observed some impairment of the sexual feeling after the Bottini operation also. Murphy had suggested that the incontinence or permanent impairment of the sexual function could be avoided by excising a portion of the prostatic urethra, thus reducing the caliber of this part of the urethra.

Dr. Willy Meyer said that, with many others, he considered prostatectomy the most radical, as well as the most surgical, procedure; in fact, it was the ideal operation for dealing with senile hypertrophy of the prostate gland. It was known that prostatic disease was dependent upon urinary obstruction, and, hence, it was rational to endeavor to control this disease by the removal of the mechanical obstruction to the outflow of urine. He had done perineal prostatectomy nine times, and had been much pleased with the results of these operations. The operation was especially indicated in hospital patients. In removing the gland he had incised each lobe separately by means of a perpendicular incision, and had endeavored to preserve, as far as possible, the ejaculatory ridge and avoid injuring the prostatic urethra. This was certainly quite a difficult task. Having tried the various modes of enucleation, he had come to the conclusion that it was desirable to have within the prostatic urethra a firm metallic instrument, which would bring the prostatic lobes within easy reach. He believed that the interference with the nerve supply might also have something to do with the impairment of the sexual function, even though the ejaculatory ridge were carefully preserved. He did not greatly fear general anæsthesia, because he had learned that spinal anæsthesia, if properly carried out, especially by means of tropacocaine, was a most excellent method. He could not confirm the statement that the convalescence from the Bottini operation was necessarily short and smooth. Prostatectomy should be the operation of choice under favorable conditions, but when those conditions could not be secured, or the patient positively refused this operation, the Bottini operation should be selected.

He had personally done the Bottini operation from October, 1897, to October, 1902, 59 times. He had been able to trace only 34 of the 59 cases. Of these 34, 28, or 82.4 per cent., were cured or materially benefited by the operation. Of 15 patients who had been using the catheter regularly before operation, 10, or 66 per cent., had laid the catheter aside permanently, and of 23 cases interviewed as to the sexual powers, it was found in 20, or 86.9 per cent., that the sexual power had been fully preserved. These results, he thought, spoke for themselves, and certainly argued strongly in favor of giving this operation a place of permanence.

Dr. Charles H. Chetwood said that he strongly favored galvano-cauterization when combined with an incision in the bladder, not only for the purpose of drainage, but to allow of an examination to determine the nature of the growth and the conditions present before and after operation. The Bottini technique had ample support, and had been successful in a commendably large percentage of cases. He desired to protest against the indiscriminate and excessive removal of the prostate gland when only a small portion of this gland was at fault. It had often been demonstrated that the removal of a small portion of the gland at the neck of the bladder was sufficient to put an end to all symptoms. Undoubtedly, a number of unfortunate results had followed too free removal of the prostate. He was personally familiar with a number of cases of vesical incontinence and fistula. He was not entirely committed to the galvano-cautery operation by the perineal route, although a number of cases had given excellent results by this method. In certain instances, an opening above the bone would give a more ready access to the gland, and allow a more complete removal of the obstructing tissue and a clearing away of the urethral orifice of the bladder. If the special technique of galvano-cauterization, with or without an opening into the bladder, lessened the risk of operation, it was entitled to high esteem in prostatic surgery.

Dr. Hugh H. Young of Baltimore said that he had had about 150 cases, divided as follows: 85 Bottini operations, 55 prostatectomies, three or four castrations, and a few miscellaneous operations. He did not ordinarily favor the operation of castration in this class of cases, but he had done it in a very few cases under very exceptional conditions. The results were good in all but nine of the Bottini operations. In 4 cases there was more or less dribbling of urine, being very severe in 2 cases. It was difficult to explain this, but he was disposed to think that it was owing to burning and scarring the sphincter as a result of some failure in the working of the irrigation part of the Bottini apparatus. Five of the patients in this series were over eighty-five years of age.

yet there were only 6 deaths. One patient had used the catheter for seven years, another for ten years, and a third for fourteen years; all of them were able to give up the use of the catheter after the operation, showing that it was entirely possible for the function of the bladder to be restored even after these long periods of catheter life. Of the 55 prostatectomies, 16 were suprapubic cases, with 3 deaths. In 3 cases the combined Alexander operation was done, without a death. In 32 cases there was one death. This occurred from embolism long after the operation, and when the patient seemed well and was on the point of leaving the hospital. He had recently done perineal prostatectomy, with a very good result, in a man of eighty-two years. There were many objections to the suprapubic operation. Among these were the fact that the operation was done entirely in the dark, the difficulty of enucleation, the greater amount of hemorrhage and the greater difficulty in draining and packing a cavity. Moreover, a cavity was left which generally communicated with a very foul bladder. For this reason convalescence was very much slower after the suprapubic method. It was now thought to be entirely unnecessary to make the suprapubic incision for pushing down the prostate, as originally suggested by Alexander. The same argument held good with regard to the Bryson method of making an incision through the skin and muscles, but without entering the bladder.

His present method of operating consisted in passing a grooved staff into the urethra, and making an incision which would cut only the central tendinous muscle of the perineum. The rectum was then pushed back and the apex of the prostate exposed. An incision was then made through the membranous urethra down upon the staff, and the instrument passed into the bladder, enlarging the opening and making way for the retractor. His own special metal retractor was next introduced, thus giving the operator great control over the prostate. It was perfectly easy to preserve the ejaculatory ducts because that region had been shown to lie well forward on the posterior surface of the prostate, and not where the obstruction was situated. If two incisions were made, leaving the bridge of tissue which surrounded the ejaculatory ducts, it would be easy to enucleate the prostate without injuring the ejaculatory ridge. Middle lobes of considerable size could be removed through one of the lateral cavities without disturbing the ejaculatory ridge at all. During the last few months he had done a number of perineal prostatectomies under spinal anæsthesia with beautiful results. In the earlier trials of spinal anæsthesia he believed the technique was faulty in that too much cocaine was used and too much fluid. He favored Morton's method, *i.e.* the introduction of dry sterile cocaine into the syringe, dissolving in a little of the spinal fluid drawn into the syringe for this purpose, and then injecting into the spinal canal this solution of cocaine in the spinal fluid. In this way no additional fluid was introduced into the spinal canal. The speaker said that he could not agree with those who thought the catheter was good enough in many cases, because he had personally never been able to keep a bladder free from infection if a catheter were used for a month, and he was sure almost every person who catheterized himself would infect the bladder after half a dozen introductions of the catheter.

Dr. HOWARD LILIENTHAL said that he had done nineteen suprapubic prostatectomies, and that of this number, one died of uræmia, which was present at the time of the operation. With these results he saw no reason for his changing to any other method of operating. Rapidity of operation seemed to him an important consideration, particularly in operations upon old people, and the incision was small and passed through unimportant structures. The incision afforded an opportunity for thorough inspection of the bladder and made cystoscopy unnecessary. In one case such inspection had enabled him to discover a carcinoma, and in another case a stone. Hemorrhage could be checked by packing the sac in which the prostate had been, not the whole bladder. These patients did not exhibit shock after this operation, and the older and more feeble ones he had had out of bed on the third day.

Dr. ALEXANDER B. JOHNSON said that his experience had been confined to the perineal operation, and the results, as a whole, had been very satisfactory. In most instances the residual urine had been reduced to a trifling quantity, and the cystitis had disappeared, but in every instance the sexual function had been greatly impaired. He agreed with Drs. Thorndike and Bangs that a considerable proportion of the intelligent patients, suffering from prostatic enlargement, could be treated satisfactorily, even for many years, by the use of the catheter. He certainly would not recommend a person exhibiting marked senile degenerations to undergo any form of prostatectomy.

Dr., PARKER SYMS said that, in the main, he agreed with the general conclusions arrived at by the previous speakers, yet he was disposed to take a more radical position with regard to the danger of catheter life. He would maintain that, with but rare exceptions, prostatic obstruction from senile hypertrophy was a very fatal disease. Of forty persons who had consulted him for this condition, and had refused operation, more than 50 per cent. died in a comparatively short time. He had done twenty-three perineal prostatectomies in succession before he encountered his first fatal case. There had been no infection in any case, but where deaths had occurred they appeared at be attributable chiefly to the anæsthetic. He believed the Bottini operation was contrary to sound and well-recognized surgical principles. He would take the ground that this operation was more dangerous than perineal prostatectomy. For example, Dr. Young's results showed about 8½ per cent. mortality from the Bottini operation, and thirty-two perineal prostatectomies without a death. Moreover, the Bottini operation could not be considered curative in a large proportion of cases. He was free to admit that the Bottini operation had yielded better results than he had at first anticipated; nevertheless, he felt that it was by no means equal to perineal prostatectomy. Dr. Goodfellow of San Francisco had performed, since 1892, by a short median incision in the perineum, seventy operations on the prostate without a death, using spinal anæsthesia largely. The danger of hemorrhage had been thought to be considerable, yet with the retractor of rubber that he had devised, the hemorrhage attending the operation amounted to almost nothing.

Dr. THORNDIKE said that eight years ago, when surgeons were doing suprapubic work for the most part, Dr. Sam Alexander of New York was advocating the perineal route, and while Dr. Goodfellow's work preceded Dr. Alexander's, he believed that the latter gentleman's persistent advocacy of the perineal route had had a great deal to do in bringing this operation to its present position of prominence.

Dr. HORWITZ, in closing the discussion, said that he was convinced that when sterility followed prostatectomy it was due to disturbance of the ejaculatory duct, but this would not explain the occurrence of sexual impotence. It should be remembered that the prostate gland was intimately connected with the sympathetic and the cerebrospinal nerves, which probably explained the occurrence of impotence after this operation. In the majority of cases it was impossible to locate with any certainty the position of the ejaculatory ducts, and, hence, they could not always be avoided during the operation. The normal position of these ducts was often very much disturbed in these cases. He had done perineal prostatectomy three times under spinal anæsthesia, and had been very much pleased with the result. He had also used a combination of oxygen and ether with much satisfaction in many cases.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held December 21, 1903.

ALEXANDER LAMBERT, M.D., PRESIDENT.

DR. FREDERICK HOLME WIGGIN presented several specimens.

A Case of Nephrectomy.—The first specimen was a kidney removed from a girl of eighteen at the City Hospital about two weeks ago. In September she was operated on for a pyosalpinx on the right side, and did well until October 24, when there was a rise of temperature to 104° F., associated with pain in the right lumbar region. The urine contained pus, and pus was obtained from each ureter by catheterization. A diagnosis of pyelonephritis was made. Chills, sweats, and fever continued. Methylene blue was administered, and was recovered from the left kidney in an hour and a half, but not at all from the right kidney, showing how extensively this organ was diseased. Accordingly, nephrectomy was done instead of nephrotomy. The operation wound healed by primary union.

Two Specimens of Appendicitis.—The first of these two specimens had been removed from a girl of fifteen who, nine days before coming under observation, had been taken with severe abdominal pain accompanied by chills, nausea, and vomiting. The operation was done at night, and an abscess, holding about ten ounces of very foul pus, was exposed and evacuated. It was not adherent to the parietal peritoneum. The cæcum appeared to be gangrenous at several points, and, hence, it was thought to be safer to remove it rather than to attempt drainage. An interesting feature was the finding of several undissolved medicinal tablets free in the abdominal cavity. This suggested the possibility of these foreign bodies having been the original cause of the appendicitis. Three hours after the operation she was apparently doing well, but after about sixteen hours vomiting set in, and she died twenty-four hours after the operation. No autopsy was allowed, so that the exact cause of death was not known, but it was probably intestinal paresis.

The second specimen of appendicitis was removed from a girl of twenty-two, who complained of pain only over the region of the gall-bladder at the time of the last attack, although there had been more or less general abdominal pain and some nausea for the past year. While under observation she had an attack of jaundice lasting three days. On doing an exploratory laparotomy the gall-bladder was found to be normal. The stomach was somewhat lower than usual, and its pyloric end showed some evidence of peritonitis. The appendix was up behind the colon. There had been some tenderness over the cæcum, but the chief area of tenderness was over the gall-bladder. The patient was recovering.

Epithelioma of the Larynx; Laryngectomy.—The larynx presented had been removed from a man, fifty-two years of age, whose knowledge of English was so limited that a satisfactory history could not be obtained. He came to the City Hospital from Bellevue Hospital wearing a tracheotomy tube. The larynx was removed without much difficulty, but the patient died forty-eight hours later with suppression of urine. The pathologist reported that the tumor found in the larynx was an epithelioma. At the autopsy the operation wound was found in good condition. There was considerable pulmonary tuberculosis, and in addition, fatty liver and chronic diffuse nephritis.

A Review of Some Statistics of Insanity.—Dr. WILLIAM MABON read this paper. He said that prior to 1888 the statistics from the various State hospitals for the insane consisted only in a presentation of such figures as the superintendent of each hospital thought best to include in his annual report. Our State had invested in hospitals for the insane the sum of twenty-two million dollars. In recent years there had been an actual increase in the number of the insane, and also in the proportion of the insane to the population. Thus, twelve years ago, there was one committed insane person to 374 of the population, while at present there was one to every 303 of the population. The average daily number of insane in the State hospitals was over 23,000, a number so large as to give considerable value to properly collated statistics. In New York State during the past year, 15.31 per cent. of the cases of insanity were ascribed to moral causes, 53.16 per cent. to physical causes, and in 31.51 per cent. the cause was not ascertained. Among the physical causes, intemperance occupied the first place; it caused insanity in over 14 per cent. of the cases admitted, and was a contributing factor in not less than 30 per cent. of all the cases received. Among the other physical causes might be mentioned pregnancy, lactation, the menopause, fevers, privation and overwork, epilepsy, epidemic influenza, sunstroke, trauma, and autointoxication. The statistics regarding the hereditary tendency to insanity were of some interest. Of over 1400 persons admitted, 17.71 per cent. gave evidence of having inherited insanity; in 50 per cent. heredity was denied, and in 31.67 per cent. it was impossible to ascertain the facts regarding its transmission. Of the 73,000 cases treated in the State hospitals since October, 1888, 22 per cent. inherited the insanity, and the percentage was higher in women than in men. The statistics forced us to the conclusion that melancholia was far more frequent than mania. Among the men 50 per cent. were single and 30 per cent. were married. Among the women 38 per cent. were single and 48 per cent. married. There were twice as many widowed women as widowed men received. It was well known that during the middle period of life alienation was the most frequent. According to the statistics of this State, the admissions between the ages of thirty and forty exceeded very largely those of any other decade, over 28 per cent. of all admissions occurring between these years. With regard to the comparative frequency of insanity in the two sexes, it should be remembered that there were special causes operating in women, *e.g.* pregnancy, parturition, the menopause, and uterine and ovarian disease. On the other hand, the predisposing causes in men were intemperance, sexual excess, and the mental strain incident to a strenuous business life. At the end of the year there were 1298 more women than men in the State hospitals. The average duration of life in the hospitals for the insane was greater in women, and more men recovered than women. Of the 7619 admissions, only 112 led professional lives. Under hospital treatment it was found that there was a slightly better chance for ultimate recovery in acute mania than in melancholia. The recovery rate was 24.6 per cent., and the death rate a little over 5 per cent.

Dr. JOSEPH COLLINS thought the majority of those not in asylum practice would not now classify cases as mania and melancholia, and that the apparent changes in the number of cases of melancholia and of insanity, and in the proportions of recoveries in these diseases were chiefly due to differences of classification rather than any actual change of type. The statistics regarding the social condition in its relation to insanity tallied quite closely with those bearing upon neurological disorders. The speaker thought we could not yet congratulate ourselves in any way upon the progress made in dealing with the insane in this country. In this State alone there was one insane patient to every three hundred inhabitants, and yet the three hundred sane persons were making no adequate provision for the care of the insane. There was no place, he declared, in this State, or in this country, where the acutely insane were properly treated. There were many asylums, but in none of these was there any proper facilities for treatment, except the Shepard Asylum in Baltimore. There were fine buildings and fairly equipped laboratories, but no proper means for the treatment of the acutely insane. The reform that we, as physicians, were

called upon to institute, was the establishment of hospitals, not asylums, for the treatment of the mentally sick in every large city in this country. He would venture to say that at least one-third of the cases seen at the pavilion for the insane at Bellevue Hospital could be distributed around in hospitals iand treated with advantage.

With regard to the differentiation between insanity and delirium due to other causes, a topic brought up incidentally, Dr. Collins said that if there was no such thing as *delirium grave*, then the question became comparatively easy. We all knew that in certain of the acute infectious diseases, best represented by pneumonia, typhoid fever, erysipelas, ulcerative endocarditis, there supervened a delirium, which was by no means very characteristic of the special disease in connection with which it developed. Prior to the introduction of quinine in the treatment of malarial fever, this disease was one of the most common of those giving rise to delirium. There were comparatively few American psychiatrists who had seen much of *delirium grave*. Personally, he had never seen a pure example of it; the cases seen at the present time, which resembled it, were called acute hallucinatory mania, associated with profound confusion, and they did not often terminate fatally. As to the treatment of the various forms of delirium, Dr. Collins said, the only method which was of the slightest service was that by stimulation. In general, this method might be said to consist in giving nourishing and stimulating enemata, and if this was not sufficient, to resort to saline infusion. Of course, rest and sleep must be secured, and the body temperature must be kept within proper bounds.

Dr. ALEXANDER LAMBERT called Dr. Collin's attention to the fact that the Baltimore asylum mentioned by him was not the only place in this country where the acutely insane might receive proper treatment, for there had been a psychopathic ward in operation for the past two years in the New York Infirmary for Women and Children, and this ward was open to physicians who desired to treat patients there.

With regard to the scientific investigation of insanity, Dr. Lambert said that such an undertaking had been started by Dr. Macdonald in the Pathological Institute, but the Legislature, which voted millions for the hospitals for the insane, objected to spending $32,000 for the work of this institute, even though this modest sum included the cost of maintaining the New York City offices of the Commission in Lunacy. It was sad to think that the real death-blow to that institute had been inflicted by three medical gentlemen from other States. He wished to say that probably only by the study of the living brain in action—the true study of psychology—would our knowledge of insanity be materially augmented. It must be admitted that the State had made great advances, from a humanitarian point of view, for our insane were now given homes in which they could live with fair comfort for the rest of their lives. The next step, which must come in time, was the proper treatment of insanity in the acute stage.

Dr. MABON closed the discussion. He said that the acutely insane were certainly scientifically treated in the McLean Hospital, in Massachusetts, in the Buffalo Hospital, in the Hudson River State Hospital, and in various other State hospitals, including the one at Ogdensburg, of which he had formerly been superintendent. He had been in the State hospital service for seventeen years, and was familiar with what had been accomplished, as well as with the shortcomings. It should not be forgotten that a very large proportion of those coming to the State hospitals were already chronic. An effort was being made to separate the acutely insane and concentrate the medical service in that department, with the object of giving adequate treatment.

THE WESTERN SURGICAL AND GYNECOLOGICAL SOCIETY.

Thirteenth Annual Meeting, Held at Denver, Col., December 28 and 29, 1903.

THE association met at the Brown Palace Hotel, under the presidency of Dr. Alexander Hugh Ferguson of Chicago.

Carcinoma of the Lung.—Dr. W. W. GRANT of Denver, Col., read a paper on this subject in which he reported two cases, one of which recurred after an unusually long interval, and having at one time coincident tubercle bacilli, and occurring several years ago. The other was recent and seemingly primary.

Pancreatic Cyst.—Dr. GRANT gave the clinical history of a case of pancreatic cyst. He spoke of the causes of pancreatic cyst, reviewed the literature of reported cases, which showed convincingly that the disease was essentially surgical, and that delay in operating was as dangerous and fatal as in appendicitis. The gangrenous cases could only be saved by promptly opening the abdomen and draining. Formerly and recently reported cases in the *Annals of Surgery* by Woolsey, which seemed unfavorable for operation, amply attested this. The suggestion in the treatment of the sac was to dissect it out if small, but in the case of a large sac this attempt was manifestly unsafe and dangerous. The extensive adhesions made it exceedingly difficult, and extravasation of pancreatic juice or septic material would probably destroy the patient; patients had died from this treatment. To attach the sac to the abdominal peritoneum, if not already adherent, and drain, was safe, and undoubtedly the best treatment of a large cyst. Pancreatic juice out of its normal channel produced fat necrosis. Pancreatic disease often simulated intestinal obstruction, and the statement might be safely accepted that if the surgeon opened the abdomen and did not find obstruction or perforation of the stomach, but observed fat necrosis, the pancreas was, in all probability, the source of the trouble.

Dr. M. L. HARRIS of Chicago spoke of the great value of colonic distention of the intestines. In going over the literature of pancreatic cyst he found that in 95 per cent. of the cases the transverse colon took a distinct circle below the tumor and the stomach above. There was practically no other tumor or cyst in which this relation was found.

Dr. Grant, in closing, said several writers had considered the differential diagnostic point mentioned by Dr. Harris, but when it was remembered that cases of pancreatic cyst were more frequent in very fat subjects, and that there was quite uniform distention of the intestines, the stomach not being so much distended because of the pressure of the tumor, or, if so, it was entirely out of its normal location, it was difficult, if not impossible, to isolate the transverse colon and the stomach. He had never succeeded in getting any benefit from artificial distention in other cases, although he did not try it in this case.

Accidental Perforations of the Uterus.—Dr. D. S. FAIRCHILD of Des Moines, Iowa, said that the use of the sound and the curette in gynecological practice was probably the most frequent cause of this accident in legitimate practice. The facility with which the sound could be used in exploring the interior of the uterus and in repositing a retrodisplaced organ was no doubt responsible for some of these accidents. The curette, however, was often used in an indiscriminate manner and as a routine treatment in a great variety of uterine difficulties that could be better treated by other means with a greater prospect of permanent results. He mentioned a case that came under his observation this year which illustrated the ease with which a perforation of an apparently healthy uterine wall could be accomplished, and what was needed in cases of this kind.

Dr. DONALD MACREA of Council Bluffs, Iowa, mentioned a case in which the upper part of the cervix, not the fundus

of the uterus, was perforated by a modified Goodell dilator by a young practitioner, and a portion of the intestine pulled through the opening and pulled off.

Dr. C. H. WALLACE of St. Joseph, Mo., spoke of a case in which a young physician perforated the uterus posteriorly with a curette at about the internal os, producing sepsis and death.

Dr. H. G. WETHERILL of Denver, Col., said the great dangers associated with the use of the curette were beginning to be appreciated both by the profession and laity, not only in the hands of the inexperienced, but in the hands of experts. He detailed a case which illustrated the ease with which the uterus could sometimes be perforated. He referred to the classic case of a woman who attempted to induce abortion by inserting an umbrella ring into the uterus, which went through the posterior vaginal wall, and, when discovered, it was found to have perforated the liver, the diaphragm, and was found in the right pleural cavity.

Dr. W. L. BULLARD of Pawnee City, Neb., mentioned two cases of perforation of the uterus, one of which was produced by a crochet hook of the ordinary size. An attempt was made to find the hook, but without avail. The patient was left alone. Six months after this she became pregnant, and the crochet hook was discharged through the anterior abdominal wall. Two months later the product of conception was expelled in the natural way.

Dr. Fairchild, in closing, said his object was not to relate unusual cases of perforation of the uterus, but simply to give expression to an opinion that he had held for some time, namely, that the curette was a more dangerous instrument than it was generally thought to be by the general practitioner. Men of great experience would not use the curette indiscriminately or carelessly, but there were many general practitioners who thought it was so essential and felt they could not do their patients justice without employing it, consequently the instrument was very often used indiscriminately.

Treatment of Gastric Ulcer.—Dr. H. D. NILES of Salt Lake City, Utah, in a paper on this subject, presented the following conclusions: (1) Post-mortem statistics, clinical experience, and recent operating-room observations all tend to confirm the belief that neither the frequency nor the grave importance of gastric ulcer is fully appreciated by the profession generally, and the majority of cases are not recognized as such in life. (2) An earlier and more positive diagnosis means greater alertness in our observation and interpretation of symptoms, and more frequent exploratory operations. (3) In the history of every benign or malignant ulceration situated in a safely accessible region, there is always a time when the pathology can be corrected or favorably modified by appropriate mechanical means. (4) Up to the present time the recognized indications for operative procedures in gastric ulcer have been the symptoms produced by the remote resultant pathology, as hemorrhage, perforation, pyloric obstruction, cancer, etc., but our aim in the future should be to make an earlier diagnosis, and by the timely application of a rational treatment prevent the occurrence of these later and more serious manifestations of ulcer. (5) Taking into stricter account the local etiological factors will undoubtedly aid us in the prevention, diagnosis, and treatment of gastric ulcer. (6) The causative pathology deserves more consideration in the surgical treatment of gastric ulcer than it has yet received. (7) Perforation always demands the promptest surgical interference. (8) Hemorrhage from gastric ulcer is best treated by gastro-jejunostomy. (9) Open or cicatrized ulcers near the pylorus always indicate rest for the parts and a sufficient outlet for the stomach contents. (10) A posterior gastro-jejunostomy with sutures accomplishes these objects with the minimum risk and the most satisfactory results, and hence should usually be the operation of choice. (11) Our future advancement in the treatment of gastric ulcer must come from an earlier recognition and better understanding of the antecedent, coexisting, and resultant pathological processes rather than from any further refinements in operative procedures.

Etiology, Symptomatology, and Diagnosis of Gastric Ulcer.—Dr. FRANK C. DAVIS of Des Moines, Iowa, said that clinically the simple ulcer was not so frequent as the statistics of post-mortem examinations would lead one to expect, being from 6 per cent., as diagnosed by Lebert, to .82 per cent., as observed by Fenwick. In the extensive records collected by Welch, ulcer cicatrized or open was in about 5 per cent. of persons dying from all causes. Fenwick, from the examination of nearly 48,000 post-mortem records, found scars or ulcers in 4.2 per cent., and in 20,000 autopsies of persons dying from various causes, open ulcer in 1.5 per cent. If one took even the lowest percentage as found post-mortem, namely, 1.5 per cent., it would be seen that every other case was undiagnosed in life. Clinically and pathologically the author classified gastric ulcer as acute, acute secondary, and chronic. Each classification was expatiated upon. Hæmatemesis was a sign of such unmistakable value that one only needed to exclude a few other sources for the blood to establish a diagnosis by it alone. The symptoms of acute and chronic ulcer were detailed. A conservative estimate of perforation placed it at about 5 per cent. It occurred most frequently in females, which might be accounted for by the fact that many more women suffered from the acute ulcer, and that the chronic ulcer developing from the acute was more liable to perforation. The accident might occur suddenly or be preceded by an increase of pain and vomiting, or by a vomiting of blood.

Perforating Gastric Ulcer.—Dr. ARCHIBALD MACLAREN of St. Paul, Minn., said that perforating gastric ulcer was fully as common as extrauterine gestation, and that when the eyes of physicians were opened to this fact, they would be able to see them, diagnose them early, and save many lives that were now lost. In this country he did not believe that the perforation cases reached the hospitals as often as they did abroad. His experience led him to believe that Dr. Richard Harte was correct when he said that rigidity or tension of the abdominal muscles was the keynote to the early recognition of peritoneal perforation from whatever source. The pain might subside, the temperature might not be elevated, but the rigidity continued even up to the end. He believed that many cases could be correctly diagnosed, as was proven by a few cases which he reported, and by the many cases which were constantly being published in the journals. He reported three cases. The first was a perforating latent gastric ulcer on the anterior wall. Operation was done eleven hours after perforation had occurred, with recovery of the patient. The second case was one of probable perforating gastric ulcer, followed by death in twenty-nine hours, either without operation or post-mortem. The third was a case of subacute perforating gastric ulcer, which was operated on nine hours after perforation, with recovery.

Dr. CHARLES W. OVIATT of Oshkosh, Wis., mentioned the case of a man, sixty-two years of age, a laborer, who had never complained of any symptoms of gastric ulcer. He had eaten a hearty meal, laid down on the lounge feeling perfectly well shortly after, but within an hour he rolled over on to the floor with agonizing pain. A physician was called, who gave large doses of morphine hypodermically, without any benefit, and the patient died within a few hours. Post-mortem examination revealed a perforating ulcer in the posterior wall of the stomach, which seemingly had attempted to heal. There was no blood in the stomach, but the abdominal cavity was filled with stomach contents.

Dr. B. B. DAVIS of Omaha, Neb., referring to the etiology, said that stagnation accounted practically for a large proportion of cases of gastric ulcer, and with-

out it there was no ulcer. This stagnation might be due to a variety of causes which he pointed out.

Dr. LEONARD FREEMAN of Denver, Col., reported a case he observed some time ago, in which perforation occurred early in the morning, but rigidity of the muscles of the abdomen did not follow until two o'clock in the afternoon. This led to a non-recognition of the case, and although operation was done, it was too late to do any good.

Dr. H. A. SIPTON of Milwaukee, Wis., mentioned five cases of gastric ulcer and one of duodenal ulcer. No diagnosis was made in three of them. He had operated on but two cases, the diagnosis in these having been made within twelve hours, one of whom died, the other recovering.

Dr. CHARLES H. MAYO of Rochester, Minn., said that after examining 1100 stomachs by test meals, laboratory testing and physical examination, anæmia was a very important factor; next, long-continued neurasthenia symptoms. He mentioned one authority who, in examining 2200 cases at autopsy, found that 20 per cent. of women showed signs of ulcer of the stomach, and only 2½ per cent. of men. Welch, in an examination of 800 cases of gastric ulcer, found 60 per cent. in women, and 40 per cent. in men. The speaker and his brother had operated on approximately 400 cases, and of 1500 cases of stomachs examined, they had found that the proportion was about the same as that given by Welch. Welch also found in an examination of 788 cases of ulcer of the stomach that only twenty-eight occurred in the greater curvature, so that the greater proportion of them were found in the pyloric end of the stomach. Of cases of cancer of the stomach, Dr. Mayo had elicited a history of chronic ulcer covering a period of from one to fifteen years. His statistics showed 88 per cent. of gastric ulcer, and 12 per cent. of duodenal ulcer. The tendency was more and more to class the first two and a half inches of the duodenum as a part of the stomach. In thirty-one cases of acute perforation of the stomach and duodenum, eleven occurred in the duodenum in this first two and a half inches, and he had operated on twenty-six cases of ulcer of the duodenum.

Dr. M. L. HARRIS of Chicago said the extensive experimental work of Fütterer showed it was impossible to produce gastric ulcer in an animal until the hæmoglobin of the blood had been reduced below a certain point; that all lesions of the mucosa produced in healthy animals readily healed. When the hæmoglobin was reduced below a certain point, producing a marked anæmia, then these lesions developed into typical ulcers. These observations showed the importance of an examination of the blood in these cases. Another point was the examination of the fæces for hæmatin crystals, as a means of diagnosis in obscure cases of gastric ulcer.

The Treatment of Hæmatemesis by Gastroenterostomy.—Dr. F. GREGORY CONNELL of Leadville, Col., in a paper on this subject, classified the operative treatment of hæmatemesis into direct and indirect. Under direct he included (1) excision of the ulcer; (2) partial gastrectomy or pyloroplasty; (3) ligation of the principal artery; (4) cauterization or curettage of the ulcer; (5) ligation of the mucous membrane, and (6) ligation of all coats. Under the indirect he mentioned (1) gastroenterostomy; (2) pyloroplasty; and (3) gastrotomy. After considering the direct method as a whole, he stated that these were not in common use, because of such objectionable features as the difficulty of locating the ulcer, the fact that the lesion was frequently multiple, the presence of firm and complicating adhesions, and the indistinct limitations of the pathological tissue. The high mortality rate of some and the impracticability and unreliability of others had been the cause of a general turning to the indirect method, as exemplified by gastroenterostomy. The manner in which a gastroenterostomy allowed an ulcer to heal was well understood and practically settled, but as to this same operation acting as a hemostatic measure, no such substantial reasons as those advanced for the healing could be presented. While rest and drainage undoubtedly favored clotting and the cessation of hemorrhage from small blood-vessels, it was difficult to understand how they could arrest hemorrhage from a large artery with a lateral opening, as in the case reported. As one was unable to determine with any degree of accuracy the nature or the source of the hemorrhage, gastroenterostomy was indicated only after a thorough search for the bleeding point. The exact status of gastroenterostomy in hæmatemesis was not well defined, as was shown by numerous quotations. It had been said that a search for the bleeding point was futile, harmful and unnecessary, and that a gastroenterostomy would without doubt prevent recurrence of the hemorrhage. To show that gastroenterostomy would, without doubt, prevent recurrence of the hemorrhage, the author reported one case and cited others from the literature. Gastroenterostomy was indicated in hæmatemesis (1) after a thorough search had failed to reveal the source of the hemorrhage. (2) When the source of the bleeding was discovered, but in such condition as to make direct treatment impracticable or impossible. The conclusion, based upon a sad experience and a review of the literature, was an endeavor on the part of the author to discountenance the idea, which had become quite prevalent, that nothing was to be gained by searching for the bleeding point, as gastroenterostomy was all that would be necessary to prevent recurrence of the hemorrhage.

Two Cases of Acute Hæmatemesis in Which Gastroenterostomy Was Performed.—Dr. LEONARD FREEMAN of Denver, Col., detailed a case in which he performed a posterior gastroenterostomy. A Murphy button was employed, having the end within the stomach smaller than that within the bowel. The stomach contained bloody fluid, Recovery was uninterrupted. The button was passed on the twenty-third day. There was no further hemorrhage. About seven months later this patient suddenly died from hæmatemesis, the hemorrhages having begun about three months after the operation, small quantities of blood being frequently vomited subsequently. In the second case a posterior gastroenterostomy was done, and a Murphy button used, the ends of which were of unequal size. The stomach showed no external sign of ulcer, and no internal exploration was attempted. The organ was markedly dilated with gas and fluid. Reaction from the operation was so satisfactory that hopes of recovery were entertained; but in spite of no recurrence of the hemorrhage, death occurred at the end of fifty hours, due apparently to the great loss of blood. Autopsy revealed an ulcer as large as a watermelon seed on the posterior wall, at the junction of the lower with the upper two-thirds of the stomach. A small atheromatous artery, plugged by a thrombus, could be seen in the floor of the ulcer.

Dr. H. D. NILES believed that in cases of acute hæmatemesis any operative procedure would be attended with a high mortality. It was difficult to diagnose gastric ulcer from the external appearance of the stomach with sufficient accuracy to deal directly with it, at least to determine upon an operation. Gastroenterostomy was not, in his opinion, an infallible remedy for the treatment of gastric hemorrhage. Unless one knew positively the source of the hemorrhage before opening the stomach, he thought it was better to perform the operation before hemorrhage was dangerous.

Dr. J. E. SUMMERS mentioned a case of hæmatemesis the result of acute alcoholism. He opened the abdomen widely and found that hemorrhage came from eight or ten small erosions. He used hot water, as hot as could be borne without irrigation, and controlled the hemorrhage for a time, but it subsequently recurred and the patient died.

Dr. JAMES E. MOORE said the treatment of gastric hemorrhage by gastroenterostomy at the present time

was more or less empirical. The profession had not arrived at that point when positive statements could be made as to its value. The past history of cases showed that a considerable proportion of them not only recovered from immediate hemorrhage, but permanently without operation.

Dr. O. Beverly Campbell of St. Joseph, Mo., said in regard to the closure of the opening made in gastroenterostomy by the suture method, he had performed sixteen experiments on dogs. In twelve he used the Kocher method of suturing, and in all of them he did an anterior gastroenterostomy. The opening in each instance was quite large. The dogs were reoperated at periods of from three to six months, and at the end of three months in six cases the opening was reduced to such an extent that the index-finger could not be passed through it without a little force. In six of the cases there was almost total obliteration of the opening at the end of six months. In four there was a slight opening through which only a small probe could be passed. A vicious circle was established in 40 per cent. of the cases. These experiments showed a tendency, where there was no obstruction at the pylorus, for the opening to close, whether it was made with the Murphy button or by the suture method. A larger opening was obtained if the Connell suture or the Kocher suture was used, and in every case the speaker made a rather large opening. Six dogs, in which a vicious circle was established, began to fail in flesh at the end of about two months, and at the end of the third month they were opened and a vicious circle found. In every instance there was more or less narrowing of the opening.

Dr. Charles H. Mayo reported a case in which gastroenterostomy failed to arrest hemorrhage. During the past year he operated upon a man forty years of age, who gave a history extending over a few years of occasional stomach disturbance and vomiting of blood. By the laboratory test a little blood was found in the stomach. At the operation, in examining the stomach, he did not find any external evidence of the ulceration. The stomach was dilated. He did a gastroenterostomy, but there was more hemorrhage after it than before, and the man died at the end of four days. He was very anæmic at the time of operation. At the autopsy the intestines were found filled with blood. The gastroenterostomy was a posterior one, after the Mikulicz method, and the line of suturing was perfect. There were no large ulcers in the stomach, but there were two or three points of erosion.

Dr. D. S. Fairchild said a distinction should be made between chronic gastric ulcers which bled and fissure ulcers which sometimes gave rise to profuse hemorrhage. The chronic ulcers could be treated by gastroenterostomy, but in fissure ulcers, where the hemorrhage was considerable, gastroenterostomy was not sufficient, and it became necessary to dissect the ulcer out. A case was narrated in point.

Dr. Connell had had recently three cases of acute hæmetemesis under observation. One bled very profusely. Operation was advised, but refused, and it was thought the patient would die. But she recovered. There were no signs of ulcer. The second case was that of a child, four years of age, who had acute hæmatemesis. Operation was refused, and the child died. The third case he operated on, having in mind Monihan's advice, that it was unnecessary to search for the bleeding point, as gastroenterostomy would cause a cessation of the hemorrhage. He operated, but the patient died. From the post-mortem examination in this case he felt confident that had he made a careful examination of the stomach with the object of finding the bleeding point, he would have found it, and had the ulcer been dissected out, in all probability the patient would have recovered.

Dr. Freeman, in closing the discussion, said there were two kinds of cases upon which the surgeon had to operate: First, those in which the surgeon could take time and search for the ulcers; and if he found them, he could deal with them accordingly. The other class was illustrated by the two examples cited in the paper.

The Correction of Retrodisplacements of the Uterus.—Dr. Charles W. Oviatt of Oshkosh, Wis., in a paper on this subject, referred to the many operations devised for correcting uterine retrodisplacements. He stated that whatever the operation selected, it should permit of thorough intrapelvic work and should be one that restored the normal axis of the uterus, at the same time leaving it free to adapt itself to its normal range of motion. The operation he described as meeting these requirements was that devised by Dr. Geo. H. Noble of Atlanta, Ga. A description of the Noble operation could be found in medical literature. During the last year the author had made this operation twenty-three times. In all but three there were intrapelvic or other complications. In ten the appendix vermiformis was removed either because of a history of definite recurring attacks of appendicitis, or because from its appearance it was deemed wise to remove it. In one case a broad ligament cyst was removed, and in several diseased appendages were taken out. These were mentioned to show that there was no difficulty in doing any necessary intrapelvic work through the transverse incision and separation of the recti muscles. In all the cases, local office treatment by means of tampons or pessaries had been resorted to without relief. Most of the cases were in women who were obliged to work and who preferred to undergo an operation rather than submit to further treatment. The three uncomplicated cases were marked neurasthenics with dysmenorrhœa. While the displacement remained corrected, there had as yet been no improvement in the dysmenorrhœa, and little or none in their general condition. There were no deaths or serious complications following these operations. The advantages of the operation were: Through the one incision any pelvic complication might be treated. The operation utilized the strongest part of the round ligament instead of its distal end. The normal mobility of the uterus was not disturbed, and it was left in the pelvis where it belonged. It caused no bladder irritation and no dragging because the traction on the ligaments was in the direction of their natural course. The writer then quoted Dr. Noble, as follows: "The anchorage is superior in permanency to all peritoneal attachments; the uterine portion of the ligament will not stretch away. There are no sutures in the fundus to irritate the uterus. The fixation is extraperitoneal. No irritated point invites subsequent adhesions to abdominal viscera. The peritoneal investment of the ligament is not drawn into the abdominal walls, producing funnel-shaped depressions and inviting hernia. It does not interfere with the physiological development of the uterus during pregnancy."

The Surgical Treatment of Goiter.—Dr. Charles H. Mayo of Rochester, Minn., in discussing this subject, said that the respect American surgeons held as to the ability of Continental surgeons was to a considerable extent due to their statistics on goiter. To the peculiar formation of the capsule of the thyroid were due many of the symptoms occasioned by enlargement. Closely investigating the gland, it divided posteriorly and also enclosed the trachea, œsophagus, and part of the pharynx. Accessory glands were not uncommon in the lines of inversion from the pharynx in the original formation of the organ. It was probable that the lymphatic system acted as its duct, and a study of the function of the lymphatics would explain some factors in the etiology of diseases of this body. In young people at the age of sexual activity, parenchymatous goiters were quite common, but, as a rule, readily responded to treatment. Reverdin, in an analysis of 3408 cases, placed the mortality from total extirpation at 19 per cent.; partial, 3½ per cent.; from intraglandular enucleation, at .78 per cent.; from resection at 6.6 per cent. The writer's experience was derived from 108 operations upon thyroid tumors. Of these, there were 34

exophthalmic cases, with 6 deaths; 2 malignant, with 1 death; one large lingual thyroid. Two cases presented separated tumors of the pyramidal lobe. There were 71 cases of cystic, colloid, adenomatous and mixed types of goiter operated upon, with one death, from pneumonia, on the eighth day. The recurrent laryngeal was permanently injured once, and its function temporarily impaired several times. The Kocher collar incision was ordinarily used and a free exposure of the gland made. The overlying muscles were either drawn aside or severed, according to the case. If the capsule was thickened over the local tumor, or whole gland, the Socin method of enucleation was commonly employed. If the gland retained its general form, the largest lobe, usually the right, was extirpated, frequently leaving its posterior capsule to protect the laryngeal nerve. Ether anæsthesia was usually employed. Occasionally cocaine was used locally, if there was much tracheal disturbance or severe exophthalmic symptoms. Chloroform was rarely given. All anæsthetics were preceded by a hypodermic of morphine. Some thyroidism usually followed for one to three days.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 9, 1904:

	Cases.	Deaths.
Measles	789	14
Diphtheria and croup	460	57
Scarlet fever	410	34
Smallpox	...	...
Varicella	122	...
Tuberculosis	301	158
Typhoid fever	42	10
Cerebrospinal meningitis	...	5

Acute Amygdalitis; Its Treatment by the Local Application of Tincture of Iodine.—Samuel Floersheim believes that the local application of the tincture of iodine is an exceedingly powerful and helpful therapeutic measure which can be positively relied upon when other remedies have failed to act. The method of application is to saturate a camel's hair throat brush with the drug, depressing the tongue with a spoon or other contrivance, and rapidly and thoroughly to paint the remedy over the inflamed area. If there is intense burning in the throat after two minutes, a simple gargle of warm water, once or twice, will give relief. Gargling should not be too frequent, as some burning is necessary to obtain the desired result. If there is only moderate burning, a gargle is not advised. If there is no burning within five minutes after the application, the iodine is renewed. When there is marked improvement in twenty-four hours, the application is not renewed. If there is little or no improvement, a second thorough application is advised. A third application has never been required. The diet should be simple and nourishing. A free movement of the bowels nearly always gives relief.—*The Medical Council.*

The Direct Illumination of the Abdominal Cavity, the Rectum, the Bladder, and the Uterus for Diagnosis and Operation.—Ott describes a combination of posture of the patient and specula provided with small incandescent lamps at their distal extremities, by means of which he is able to secure unusually good illumina of the various cavities concerned in pelvic and abdominal surgery. With the patient in the lithotomy position the head is lowered until the body makes an angle of forty-five degrees with the horizontal, as in the lithotomy position. An incision through the posterior fornix now is followed by an inrush of air as the intestines settle toward the diaphragm, and the pelvic organs are exposed in the large space left vacant. Long specula, provided with incandescent bulbs of special construction, are placed in position, and the entire abdominal cavity and its contents, even the liver and gall-bladder may conveniently be inspected. When necessary a bulb on a long stem can be introduced deeply to facilitate the inspection of more remote regions. Every vaginal operation may be performed with as much certainty as if on the surface, and the method loses its greatest drawback, that of working in the dark. Suitably modified instruments enable the author to inspect the entire sigmoid flexure and even the descending colon, the bladder, and, under some conditions, the uterus.—*Monatsschrift für Geburtshülfe und Gynäkologie*, Vol. XVIII, No. 5.

Treatment of Acute Appendicitis.—To limit the peristaltic action of the intestines so that the patient may be carried beyond the fourth day, when operative measures may safely be taken, Ochsner advises that: the alimentary canal be relieved, the stomach washed, if there is vomiting, and the colon emptied by a high injection of decinormal salt solution. The only nourishment given is by enema. The patient is allowed no food, and is kept in a condition of absolute quiet. After the period named, the operation, if necessary, can be performed.—*Gaillard's Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended January 9, 1903:

ON CYTODIAGNOSIS IN NERVOUS DISEASES.*

By CHARLES L. DANA, M.D.,

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

WITH A DESCRIPTION OF

THE TECHNIQUE OF CELL-DIAGNOSIS.

By F. W. HASTINGS, M.D.,

INSTRUCTOR IN CLINICAL PATHOLOGY CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

THE study of the serous fluids of the body has opened up a new field of diagnosis. It is a field which, in some directions, has achieved distinct results and offers much promise for the future. In particular, the study of the cells of these fluids has been helpful and has of recent years been carried on to such an extent as to form a particular branch of diagnostics, known as "cytodiagnosis." It has not, it seems to me, been utilized in routine work in this country, to the extent which it ought, and hence, I venture to present one phase of cytodiagnostics, that particularly of the cerebrospinal fluid.

The method of lumbar puncture, as devised by Quincke,† was advocated quite as much for therapeutic as for diagnostic purposes, The study of the cells received very little attention. The fluids were examined for their gross appearances, for the ordinary microscopical appearances, the physical and chemical characters were sometimes noted, and bacterial cultures were made. By the latter method a good many interesting observations were made, and some occasional help or confirmation in diagnosis was procured. The bacterial culture of the cerebrospinal fluid have quite recently been more carefully studied, and with some very satisfactory results. For example, in the last volume of the Mt. Sinai Hospital Reports, Dr. E. Libman states that he has examined bacteriologically over one hundred cases of meningitis, in most of which the fluid was obtained by lumbar puncture. One of his conclusions is that the cerebrospinal meningitis of this country, at least, is always due to one type of organism, namely, the diplococcus of Weichselbaum, and he does not find that the pneumococcus can cause epidemic meningitis. It would seem, from his experience, that any of the pyogenic microorganisms can cause a sporadic meningitis, usually by first causing some local disease, like an otitis or a pneumonia. The recognition of tuberculous meningitis in its early stage, is also often helped by the bacterial cultures.

My own experience has been mainly with the cytodiagnosis of fluids obtained by lumbar puncture, according to Widal's suggestions. For some years I have at intervals withdrawn fluids from the spinal canal by this method, mostly in cases of alcoholism, and at first, for therapeutic purposes, thinking that the withdrawal of fluid, for example, in what are termed as "wet brains," might be of some help. Such a procedure does occasionally ameliorate the symptoms, but is of no permanent value. Having reached this conclusion, I have not until lately done the lumbar puncture, excepting occasionally in cases of meningitis for diagnostic purposes. Special interest in cytodiagnosis has been aroused of late by the reports of Widal in 1900 upon the peculiarities observed by him in the cells of the cerebrospinal fluid in different forms of nervous disease, especially in cases of syphilis and parasyphilis. Widal claimed for his method a distinct help in recognizing paresis, tabes, and in the differential diagnosis of other diseases of the central nervous system. While there have been some contradictory reports, his views have, on the whole, received support, and my own investigations so far, in a measure, confirm them. In addition, however, to the simple methods of cytodiagnosis, some prognostic and, perhaps, therapeutic help can be obtained by a chemical study of the cerebrospinal fluid, in cases of nervous disease, for the presence of neurin and cholin. It was shown in 1901 by Mott and Halliburton that in diseases of the nervous system, associated with a more or less rapid decay or degeneration of nerve tissue, there was a break up of lecithin, and as a result there was thrown out into the absorbent fluids and the blood a poisonous product of tissue waste, known as *cholin*. They suggested that it would be possible to make a practical use of this fact in establishing the presence of degenerating lesions, and also establishing the fact that these lesions were either progressing or quiescent. (See below.)

Before giving the results of my experience, I should like to say a word regarding the characteristics of the cerebrospinal fluid and the technique of lumbar puncture.

The cerebrospinal fluid lies between the arachnoid and pia mater, and permeates the ventricles of the brain, bathes the surface of the brain, surrounds the spinal cord, and perhaps leaks a little down into the spinal canal. The fluid, as is well known, flows freely from one part of the cerebrospinal axis to the other. As regards its relationship and function, the cerebrospinal fluid is a unit—that is to say, withdrawal of fluid from any part of the nerve centers, whether it be the lateral ventricles, the subarachnoid spaces of the brain, or of the spinal cord, affects at once the supply and pressure relations in other parts. The fluid exists in these cavities under a certain low pressure, varying from 40 to 60 mm. Under pathological conditions, it can rise as high as 800 mm. Its specific gravity is 1003 to 1004, varying in pathological states, from 2 to 9, or even 12. The point of congelation is normally between .72 and .78. There is little variation from this in chronic diseases, but in acute processes the congelation point falls and in tuberculous meningitis sinks to .50 or .56. The fluid is ordi-

*Read at a meeting of the Practitioners' Society of New York, December 4, 1903.

†The history of cytodiagnosis is given in an article by Dr. Fraenkel, published in the present issue of the MEDICAL RECORD. I shall not, therefore, refer to it to any extent. A very good summary of our present knowledge is given in a recent work by M. Labbé, entitled "Le Cytodiagnostic."[1]

narily like clear water, but it becomes cloudy in inflammatory processes and hemorrhagic in cases in which there have been cerebral or spinal hemorrhages. The normal amount ranges from ʒ ii to ℥ ii.

The composition of the cerebrospinal fluid, although resembling lymph and formed in the same way by transudation from the blood, differs chemically in some details. It has, for example, about one-fourth as much proteid substance and no sugar. It contains about 1 per cent. of solids and a peculiar non-nitrogenous substance which has the property of reducing copper salts, and which is, according to Halliburton, pyrocatechian. The proteid matter consists almost entirely of protoalbuminose and a small amount of serum globulin, but there is no fibrin ferment.

The normal cerebrospinal fluid contains no cells, or, at least, only rarely a mononuclear lymphocyte or an endothelial cell.

As regards the pathological constituents of the cerebrospinal fluid, it has been found that in general paralysis and meningitic processes the total amount of proteids is increased (Widal, Secard, and Ravant, G. Guillain and Parant.[1] The presence of cholin was observed by Mott and Halliburton.[2] This observation has been confirmed by others, and among these recently by Julius Donatti.[3] Dr. Hastings found it in two of my cases of alcoholic psychosis. Donatti has made an especially elaborate study of this subject, having examined the cerebrospinal fluid in 65 cases, including epilepsy, 22; general paralysis, 5; tabes, 15; brain tumor, 2; multiple neuritis, 1. He found cholin in nearly all cases. He did not find it in hysteria, 2 cases; multiple sclerosis, 1 case. He found it, however, in one case of neurasthenia, and one of hysteroepilepsy. He also found phosphoric acid in the cerebrospinal fluid. This and cholin are the results of the splitting up of lecithin. He thinks that cholin has a convulsive action on the nervous centers and is an important factor in determining the epileptic attacks. This remains to be further tested. Some observers assert that cholin is innocuous and that it is its close derivative, neurin, which is poisonous.

The technique of lumbar puncture is well known, still it is not quite so simple as it seems and needs a little experience. It is usually customary to insert the needle between the third and fourth lumbar spaces. on a line drawn between the two postero-superior iliac spines. I have often made the puncture between the second and third, and there does not seem to be very much difference in the results. Having sterilized the skin, hands, and the instruments, the part should be cocainized with 30 minims of a ½-per-cent. solution. After waiting at least five minutes, the needle is introduced one inch to one side of the median line. It should be quickly thrust through the skin down to the lamina with one motion; then having felt the end of the needle for a space between the lamina, it should be thrust quickly between the laminæ of the spine with a second movement. In this way, and with cocaine, hardly any pain is produced. The instruments usually used are what are known as the "Quincke set," consisting of a trocar, cannula, and manometer. I have, however, been accustomed to use an ordinary aspirating needle, and it answers perfectly well. It also possesses the advantage that if no fluid comes away, a hypodermic can be attached and gentle suction made. In this way, when some slight obstruction exists at the point of the needle, this can be overcome, and I have sometimes been able to secure a successful result when otherwise there would have been a "dry tap." Furthermore, it is, in my opinion, not unlikely that this method may be utilized for medicating the cerebrospinal axis. I have introduced sterilized serum in place of the serum withdrawn, hoping to avoid the headache which often follows the puncture. The lumbar puncture may be done when the patient is in the sitting position or lying on his side in bed. I do not find much difference in the success of the results; but often in a nervous patient, the movements of the body can be better controlled when he is lying in bed with the back bent and the knees drawn up. The whole procedure is unquestionably a rather disagreeable one for a few minutes, though when the needle is in, the patients have only a little dull aching, and they do not complain much even when they have to sit for five or six minutes waiting for the fluid to drop out. Every now and then—perhaps, in two cases out of twenty—no fluid will flow. Sometimes this failure does not seem to be the result of any fault in the technique, for in one patient four punctures were made and the canal penetrated, without any result. In these cases, however, the use of the hypodermic syringe, to start the flow, will sometimes prove effective. The fluid, under ordinary conditions, comes away in drops, about one or two a second; sometimes, however, it flows very slowly, only six or seven drops in a minute. It is necessary to obtain from 4 to 6 c.c. I believe that 4 c.c. is enough and the patient will be less likely to have headache later. The fluid should be dropped into the centrifuge tube, which should be previously sterilized. It should not be caught in a test-tube and then poured into the centrifuge. It must be centrifuged for ten minutes within one or two hours after the fluid is withdrawn. It cannot be kept till the next day. After this process, if there is any lymphocytosis, there is a slight cloud at the bottom of the tube. A drop of this cloudy precipitate is collected in a capillary pipette and placed on a glass for purposes of study. Dr. Hastings, who has made all the microscopical and technical examinations of the fluid, and to whom I am greatly indebted, has devised a procedure for making a systematic count of the cells seen under the microscope.

I would say, in addition, that all accounts agree as to the harmlessness of the operation, unless, perhaps, a very large amount of fluid is withdrawn, *i.e.* over an ounce, in cerebellar tumor.

I have so far made successful lumbar punctures upon twenty-two patients, suffering from the following diseases:

TABLE.	NO. CELLS.
Doubtful paresis	Few.
" "	3
Paresis	0
"	0
"	16
"	37
"	135
"	0
"	33
"	74
"	85
Double hemiplegia and paresis	74
Paresis	Numerous.
Brain tumor	Few.
Syphilis with psychosis	722
Meningitis	155
Contusion of brain	44 + red cells.
Cerebellar tumor	0
Congenital internal hydrocephalus	0
Alcoholic insanity	Few.
Karsakoff's psychosis	5
" "	3
Spinal gliosis	6
Total	22

In eight of the cases of paresis there was a very marked lymphocytosis, the number of cells in a hundred fields ranging from 16 to 135; in most cases being above 50. In two cases of paresis there were no cells found whatever, but in these cases I only withdrew about 4 c.c. and the fluid was received in a test-tube. In one case of paresis there were only

six cells found in 100 fields, and in another, only three. In all the cases of the alcoholic psychoses there were either no cells found or only 3 to 6 in a hundred fields. In the cerebellar tumor case and in the hydrocephalus case (the patients were observed by Dr. Hunt), the fluid was absolutely free from cells. In three cases, in which the diagnosis was doubtful, between that of alcoholism and paresis, cells were present in large numbers in two and absent in one case. The case of contusion of the brain was one of particular interest. Five weeks previously the patient had been struck a severe blow upon the left parietal region. He was unconscious and brought to Bellevue Hospital, where he remained for some weeks in the surgical ward. While there he was carefully observed by Dr. J. R. Hunt, who found no signs of any paralysis or any disturbance of cranial nerves, or any active inflammatory process. He was distinctly aphasic, but in addition to that he seemed to be confused, and often incoherent and rambling in his speech. There was some question as to whether he was simply suffering from the mental symptoms due to the shock in concussion of the brain, or whether he had actually had some bruising of brain tissue and hemorrhage upon the brain surface. Five weeks after his injury, I made a lumbar puncture and withdrew 6 c.c. of cerebrospinal fluid. This was perfectly clear, and showed no apparent evidence of blood. After being centrifuged for ten minutes, a deposit of red blood cells, 1 mm. in diameter, was found at the bottom of the tube. Dr. Hastings' examination of the cellular contents showed 1200 red blood cells in a hundred fields and 44 lymphocytes, mostly mononuclear. Before this examination was made, the diagnosis of the attending physicians, Drs. Packer and Gregory, was that he had a confusional psychosis, due to the shock and injury, but that he had, in addition, some organic and serious change beneath it, and the cell count would seem to indicate that this was the case, and that the man would perhaps develop an organic dementia. In other words, the prognosis was considered serious on clinical grounds, and was confirmed by the cell count. In the case of spinal gliosis, there were many symptoms pointing to multiple sclerosis, and the absence of cells enabled us to exclude this, as well as any syphilitic or parasyphilitic process.

The cytodiagnosis of the cerebrospinal fluid seems likely occasionally to be of great help in diagnosticating the doubtful cases of paresis and of tabes, in the early stage. It will also be of help in determining the question, whether or not the person has had syphilis, and whether or not certain symptoms indicating the invasion of the central nervous system by this infection are correct. In spinal syphilis, as shown in cases of syphilitic meningomyelitis, or Erb's spinal paralysis, there is an increase in the cell count, and if trauma can be excluded, the presence of specific infection may be inferred. This method of diagnosis should be of help also in determining the activity of the process. If there is any actual inflammatory change going on, it will be shown by the presence of the polynuclear leucocytes, while in the ordinary conditions of specific infection, only mononuclears are present, with a proportion of polynuclears of not over 5 per cent. Whether a further differential count will reveal anything, I cannot tell. It is said that the eosinophiles are not found in this fluid, but they were discovered in one case. It must be remembered, of course, that there are some cases in which, although paresis or tabes is present, there are no cells found, at least, on the first examination. Widal, however, asserts that if two or three examinations are made the lymphocytosis will always be discovered.

The study of the chemical constituents of the fluid, with reference to the discovery of *cholin*, may also offer help in diagnosis and prognosis.

This diagnostic method is still in its infancy, and it is possible that we are overrating its practical value, but enough has been definitely determined to justify a routine use of this method until we can speak with absolute certainty about it. There is no doubt that the operation is a disagreeable one to the patient, but by the careful use of cocaine, the skilful insertion of the needle, and the withdrawal of as small an amount of fluid as possible, very little discomfort is caused. The subsequent headache and vertigo are certainly disagreeable, but I think it not unlikely that a means will be devised of remedying this either by substituting sterilized lymph in place of what we have withdrawn, or by giving some suitable anodynes. It seems as though, in some cases, the headache is reflex or psychical, for in one patient a very severe headache followed a puncture which was unsuccessful, no fluid being found. Beside the headache which follows and lasts for a day or two, I have had two patients in whom there was a rather persistent vertigo, lasting for several days. In another patient who came in very alcoholic, and in whom the alcoholism was superimposed upon a paresis, the puncture and withdrawal of the fluid was followed by a typical but mild attack of delirium tremens that night; he was all right the next day.

Technique (by Dr. Hastings).—Among the earliest studies of cells in exudates are those of Boettcher[4] (1867), who examined, in the fresh state, purulent material from an alveolar abscess, and of Ehrlich,[5] who examined both the fresh material and dried and stained preparations from bacterial and carcinomatous pleural exudates and differentiated the cellular elements. Wentworth[6] noted the various types of cells in fresh fluid from the meninges in cases of meningitis in children. Bernheim and Moser,[7] stimulated by Quincke's reports on lumbar puncture, examined microscopically the cerebrospinal fluid from cases of meningitis after sedimentation of the fluid on standing, or centrifugation and staining with Löffler's methylene blue. They noted the presence of mononuclear cells in excess in tuberculous cases and of polynuclear cells in excess in epidemic and purulent cases, also endothelial cells in the tuberculous form. Councilman, Mallory, and Wright[8] in their report on epidemic cerebrospinal meningitis, mention the finding of three types of cells—polynuclear, mononuclear, and epithelioid—upon microscopical examination. Mallory and Wright[9] prepared specimens from spinal fluid by smearing coverslips with the sediment, after standing several hours, drying the smears in the flame of a Bunsen burner and staining with methylene blue. They stated that "in tuberculous meningitis the predominant cell is the lymphoid cell. In purulent meningitis the polynuclear leucocyte predominates." This simple technique was elaborated by Widal[10] and his pupils, who employed defibrination and centrifugation for non-purulent pleural fluids in which the cellular content is often comparatively small. After centrifugation a drop from the bottom of the tube was taken up with a finely-drawn pipette or a platinum loop, spread upon a slide, allowed to dry in the air, fixed with alcohol and ether and stained with thionin, or hematein-eosin, or fixed by heat and stained with Ehrlich's triple stain. The writer has recently seen a specimen of fluid from a carcinomatous pleural exudate pre-

pared in the above manner, resulting in the finding of typical carcinomatous tissue in small particles barely visible macroscopically.

Monod[11] tried various other methods of fixation, osmic acid, mercuric chloride, formol, chromic acid, and found Widal's methods more satisfactory.

The cerebrospinal fluid in cases not of an acute inflammatory nature is, as a rule, clear, and does not require defibrination, and after centrifugation the fluid is often still clear, even at the bottom of the tube.

Widal, Sicard, and Ravaut[12] rely upon the following technique: The spinal fluid is collected in centrifuge tubes with narrow drawn-out ends and centrifugated for ten minutes at 3000 revolutions; the centrifuge tube is inverted, thus pouring off the fluid with the exception of a small drop, which is taken up from the bottom of the tube with a capillary pipette. The entire small drop is spread out carefully in portions on three or four slides, dried in the air or in an oven, fixed with alcohol and ether, and stained with eosin hematein, Unna's blue, or Ehrlich's triacid stain. The entire drop (three or four slides) is examined, to avoid error in conclusions as to the number of cells, arising from unequal distribution. The absolute number is not determined, but the cellular elements are noted as present in more or less large quantity, and in later writings the presence of three or four cells in a field has been interpreted as indicative of chronic meningeal disturbance.

Laignel-Lavastine[13] describes the following technique for the determination of the absolute quantity of cells. When the liquid is turbid the cells in suspension are sufficiently numerous to proceed as ordinarily with the hematimeters of Hayem or Malassez. For clear fluids one centrifugates the fluid, noting the number of c.c. of fluid used: V represents this volume of fluid. After centrifugation with the least possible stirring, by means of a capillary pipette the upper layers of liquid are drawn off, the last drop taken up by the pipette being examined from time to time to assure oneself that it contains no cellular elements: V-D represents the quantity drawn off, D the amount of liquid remaining in the tube. The remaining drops containing the cellular elements are stirred to form a homogeneous emulsion, and the cellular elements therein enumerated with the apparatus of Malassez, Leitz Ocular No. ii and objectives Nos. 5, 6, or 7. (A Thoma-Zeiss counting apparatus may be used.) N represents the number of cellular elements in D per cubic mm. The spinal fluid then contains to the cubic mm. X cells; and

$$X = \frac{N \times D}{V}$$, D and V being expressed in cubic mm.

His results were verified by control test with diluted defibrinated blood containing 200 cells (red and white) per cubic mm. mixed with variable volumes, but exactly measured, of salt solution, 7.5 grams to 1 liter. Estimations of the number of cells by the centrifugating method gave very nearly the same results as obtained by accurate dilution and careful counting with blood instruments.

Widal apparently does not consider such exact enumeration necessary, the various formulæ representing the predominating type of cell—lymphoid, polynuclear, or epithelioid—being the important determinations.

Hand,[14] in reporting successful examinations for tubercle bacilli in spinal fluid, emphasizes the importance of a proper technique to obtain preparations satisfactory for examination for tubercle bacilli, and at the same time notes the difficulty or impossibility of obtaining preparations satisfactory for differential counting by heat fixation, owing to distortion of cells.

Descos[15] in a review on cytodiagnosis, describes the technique in full, and recommends wet (fresh) preparations for least distortion and fixation by alcohol and ether and staining with hematein-eosin for dry preparations. He mentions the use of iodine solutions for determination of Ehrlich's glycogenic reaction.

Many of the various blood-stains have been used for the dried smears, and all the varieties of normal blood-cells, excepting the mast-cell, have been found in cerebrospinal fluids. Musgrave[16] used Leishman's stain for preparations from pleural exudates.

The method employed in examination of fluids from Dr. Dana's cases was as follows: The spinal fluid is collected directly into sterilized centrifuge tubes to avoid cell contamination and disintegration of cellular elements, brought about in part at least by bacterial action often occurring in imperfectly cleansed tubes, similar to the disintegration of casts by bacteria in urine containing various forms of bacteria from outside contamination.

As a rule the fluid is examined within two hours after tapping, although in sterile tubes the cells in the fluid remain intact 24–48 hours, with no variation in the number of cells. Six (6) c.c. of fluid are centrifugated at 1800 to 2400 revolutions a minute for fifteen minutes, revolutions above 1800 resulting in little or no variation in the number of cellular elements in a capillary drop after fifteen minutes' centrifugation. After centrifugation the tube is inverted, the fluid thus poured off, and from the small amount of remaining fluid a drop is drawn up in a capillary pipette, blown out on a slide, covered with a seven-eighth-inch coverslip and examined with a Leitz No. iv ocular, No. 7 objective.

For sedimenting and centrifugation Napp's[17] two-piece centrifuge tubes may be used, but with no advantage over the use of a capillary pipette.

For estimating the approximate number of cells in the drop spread over a fixed area an Ehrlich's eyepiece with the widest field is used, the total number of cellular elements, excepting red cells, viz., mononuclear cells and polynuclear cells in 100 fields is recorded and the average for one field estimated. Thus the cells are counted over approximately the same area for every specimen and without manipulation other than centrifugation. The variation in number of cells at periphery and at center of the covered drop is practically nil. Estimating the relative number of cells in fresh, wet specimens gives results slightly below those obtained by counting the cells per field in the dried and stained specimens.

In negative (normal) specimens a careful searching over 3–6 slides may reveal a few (under 10–12) lymphoid cells and red cells.

For differential counting the drop of centrifugated fluid is mixed with a drop of Löffler's methylene blue, and if the cells are sufficiently numerous 100, 200, or more cells are counted differentially, being classed as polynuclear, small mononuclear, and large mononuclear; rarely typical large epithelioid cells are found and classed as such. For the purpose of differentiating eosinophilic and other granulations, drying, fixing, and staining, as recommended by Widal, are necessary. Specimens dried in the air and stained with Jenner's, Leishman's, or Wright's stain give good results, but since the cytologic formulæ are based upon polynuclear, mononuclear, and epithelioid types of cells, the study of such preparations is of little value.

While all types of normal blood cells, excepting the mast cell, have been found in spinal fluid, the value of the differential count lies in the determina-

tion of the relative proportions of polynuclear and mononuclear elements—the determination of a polynucleosis or of a mononucleosis—and a division of the mononuclear forms into "small" and "large" is unnecessary.

In the cases considered the approximate determination of the number of cells is important.

LYMPHOCYTOSIS OF THE CEREBROSPINAL FLUID.*

By JOSEPH FRAENKEL, M.D.,
NEW YORK.

The study of the corpuscular elements of exudates and transudates of serous membranes is of recent date and promises diagnostic aid. French authors in particular have contributed to the question of cytodiagnosis. On the basis of their studies, Widal and his followers have elaborated the following formula: (1) Increase of mononuclear leucocytes suggests the tuberculous nature of the disease. (2) Increase of polynuclear leucocytes (neutrophiles and eosinophiles) bespeaks an acute infectious condition. (3) The presence of endothelial cells points to a mechanical origin of the fluid.

The study of fifty cases led O. Kose to make similar statements. Opinions contradictory to or modifying the above formula are also reported: (Czernot-Schwartz, J. Bronstein, Litten, M. Wolff). L. Concetti formulates his opinions in this respect thus: "Predominance of lymphocytosis is the expression of toxic, predominance of polynuclear leucocytes, of bacterial irritation."

In January, 1901, Sicard, Widal, and Ravaut reported the results of their systematic cytological examinations of the cerebrospinal fluid of 134 cases. They found lymphocytosis in 17 cases of general paresis, in 6 cases of syphilitic meningomyelitis, in 14 cases of tabes, in 2 cases of multiple sclerosis, and what seems to be an interesting finding in 7 out of 11 cases of herpes zoster. The lymphocytosis was absent in cases of syringomyelia, old hemiplegia, poliomyelitis, neuritis and other peripheral palsies, Friedreich's ataxia, neurosis, and what seems remarkable, in cases of compression myelitis.

Armand-Delille and Camus studied the cerebrospinal fluid in 13 cases of tabes from Déjerine's clinic. They found lymphocytosis in only 4 cases. In the discussion which followed the presentation of this report at a meeting of the Société de Neurologie of Paris, surprise was expressed by Babinski and Dufour. Déjerine stated that in his experience lymphocytosis may be absent in the courses of tabes. Achard and Grenet found no lymphocytosis in 2 cases of general paresis. Widal, Sicard, and Ravaut reported later another series of examinations—37 cases of tabes—in 36 of which lymphocytosis was marked. Schoenborn examined a number of cases in Erb's clinic and reports a general confirmation of Sicard's results: From 8 cases of tabes, 7 showed marked and one moderate lymphocytosis. Progressive muscular dystrophy, paralysis agitans, glioma of the cerebellum, neuritis and compression myelitis showed absence of lymphocytosis.

With the aid of Drs. Wachsman and Heimann of the staff of the Montefiore Home, I have attempted to obtain cerebrospinal fluid from 47 cases. In 14 cases the tapping was unsuccessful, *i.e.* no fluid could be obtained. The failures occurred mostly at the beginning of the examinations and were apparently due to faulty technique. Among the 33 successful punctures there were: 7 cases of tabes, 4 of general paresis, 3 of syphilis of central nervous system, 7 of multiple sclerosis, 2 of paralysis agitans, 1 case of doubtful paralysis agitans or diplegia, 3 cases of brain tumor, 2 of hysteria, 1 case of poliomyelitis, 1 with discharge of the cerebrospinal fluid from the nose, 1 of aural vertigo with peripheral facial palsy, and 1 of hereditary syphilis without nervous symptoms.

The seven cases of tabes represented mostly cases of long duration; a more or less marked increase of the lymphocytes was found in all of them. In one case, however, the fluid was hemorrhagic, and therefore it is difficult to state whether the lymphocytosis was not purely the result of the bloody admixture. In some cases, only a few, five or six leucocytes were found in each field; in others they were not countable. In all cases leucocytes were preponderant; in only two polynuclear cells were seen.

Of the four cases of general paresis leucocytosis was marked in three cases and in one (a recent case) no lymphocytes were found in the fluid. The polynuclear cells were found markedly increased in only one case.

In six out of the seven cases of multiple sclerosis marked leucocytosis was found. In these cases no polynuclear cells were ascertained.

Of the three cases of syphilitic disease of the central nervous system two showed marked leucocytosis. The relation of the mononuclear to the polynuclear variety seemed here to be in favor of the latter.

In one case of brain tumor with a clear history of syphilitic infection, leucocytosis was found.

In all the other cases the fluid was found free from corpuscular elements.

It is needless to state that scrupulous antiseptic precautions are to be taken during these examinations. An ethylchloride spray minimizes the pain and prevents the occurrence of disturbing contractions and movements. The tapping is best performed on the patient in a sitting posture, slightly bent forward, or if in bed, turned over to one side. The most suitable space is between the third and fourth lumbar vertebræ. A line drawn from the highest points of the iliac bones crosses the vertebral column between the third and fourth vertebræ. In my experience it is best to introduce the instrument at this height quite near the middle line; so one can best avoid striking the roots or having the instrument clogged by the same. Occasionally one has to wait thirty seconds to a minute until the fluid appears. I have used the Stadelman trocar in preference to an aspirating needle; aspiration being looked upon as not quite safe.

*Read at a meeting of the New York Neurological Society, January 5, 1904.

We have gauged the pressure of the cerebrospinal fluid empirically by observing the speed of the flow We have found that this varies in an unaccountable manner from a speed of 4 drops a minute to squirting. The first few drops are not collected; if the fluid is bloody it is best to wait until it clears. From 5 to 8 c.c. of the fluid are collected in a sterile centrifuge tube. Pouring the fluid from one tube to another is to be avoided. The fluid is centrifuged for ten minutes, then carefully decanted and by means of a capillary pipette, a drop is taken from the bottom for examination; this drop is dried at room temperature, fixed with equal parts of alcohol and ether, stained (Jenner, Goldmark), and examined.

Usually the cerebrospinal fluid is supposed to contain very few or no corpuscular elements (three to four in a field). When there are more, one may speak of an increased lymphocytosis.

A positive diagnostic inference cannot be made, as far as my investigations go, from the prevalence of one or the other type of corpuscles.

From the purely chemical standpoint the cerebrospinal fluid has not been thoroughly investigated. Guillain and Parant believe to have found an increase of the coagulable albumoses in cases of general paresis and look upon this as a valuable prognostic sign. According to Donath, cholin has been found in the blood and cerebrospinal fluid in those diseases of the nervous system which are associated with destruction of the medullary sheath (cholin being a derivative of lecithin). The presence of reducing substances is believed by some to be of occasional diagnostic value.

Concerning the dangers and after-effects of lumbar puncture for diagnostic purposes, it need be stated that in only one case was the immediate effect of the puncture somewhat threatening. This happened in a case of supposed cerebellar tumor. Immediately after the introduction of the cannula the patient went into a collapse, from which he was revived with some difficulty. No fluid escaped, and it appeared that this accident was due to a sudden medullary concussion caused by the fluid impinging violently upon the medulla in its attempt to reach the lower level and having been apparently prevented. This is in harmony with Quincke's warning to avoid lumbar punctures in cases of cerebellar disease or disease of the posterior fossa. The cases recorded in literature in which death was the result of a lumbar puncture were mostly cases of such nature. It is well to draw attention here to Oppenheim's experimental investigation, according to which minute hemorrhages around the central canal have been observed in animals after lumbar puncture.

In a number of other cases headache and nausea appeared. In most of these cases this symptom was easily overcome by saline injections; in one case it proved somewhat troublesome for an entire week. Finally it may be mentioned as a curiosity, that a therapeutic success is reported to have followed an intraspinal injection of colloidal silver in a case of meningitis.

THORIUM: A RADIOACTIVE SUBSTANCE WITH THERAPEUTICAL POSSIBILITIES.

By SAMUEL G. TRACY, B.Sc., M.D.,
NEW YORK.

The marvellous properties of radioactive substances have made them a matter of great interest to all scientists, but to the medical man their possible value as therapeutic agents renders them objects of special and peculiar importance.

There are but four known elements which are radioactive. These are radium, thorium, polonium, and actinium. The latter two I will not consider here, as they are the least known, extremely rare, and almost beyond the power of purchase. Radium I have already dwelt on in previous papers.* Thorium is one of the rare metals, and was discovered in 1828 by Berzelius. Until the past few years, it has been too rare and expensive to be used commercially or in medicine. It is now, however, more abundant, and is found in certain sands in North Carolina, in Brazil, and in Norway and Sweden. The most active thorium is obtained from the minerals cleveit, broggeri, monazite, in the order given. During the past ten years it has been used as the principal chemical for the production of incandescence in the Welsbach mantle.

Since the discovery of radium by Professor and Madame Curie, renewed interest has been excited in thorium, because it has been found, by Prof. G. C. Schmidt, to possess the property of radioactivity.

Fig. 1. Thoriograph taken in a dark closet with three broken Welsbach mantles. Time of exposure, 72 hours.

That thorium is, in fact, radioactive, is susceptible of demonstration in two ways: First, by means of a delicate electroscope, such as is used in demonstrat-

*New York Medical Journal, October 24, 1903; New York Journal of Advanced Therapeutics, December, 1903, and New York Medical Journal, January 9, 1903.

ing electrical induction; and, second, by means of the sensitized photographic plate. With the first method, when a preparation of thorium is brought near the wire attached to the two gold leaves in the electroscope, the leaves fall together, thus indicating the presence of radioactivity. The greater the rate of the discharging power of the leaves, the greater the radioactivity.

The second test—that with the photographic plate—takes a much longer time for its accomplishment, viz., from twenty-four to forty-eight hours, if a screen made from the nitrate of thorium is used; but when hot emanations from the oxide of thorium are the excitant, a photograph may be obtained in one hour. Among the first thoriographs that I obtained was one taken by three Welsbach mantles. In a dark closet I placed a photographic plate. Upon this was laid a pair of scissors, as appears in Fig. 1, and on top thereof, three old Welsbach mantles, rich in thorium oxide. In seventy-two hours I obtained a good negative. In other thoriographs I have taken, I employed a screen of thorium oxide—using simply a piece of pasteboard—to which I added mucilage and dusted on it a thin layer of thorium. Thoriographs were taken by this method in from twenty-four to forty-eight hours. See Figs. 2 and 3.

The most penetrating Becquerel rays are those obtained from hot thorium oxide. The thoriograph shown in Fig. 3 was obtained by taking a photographic plate, covering it with thick black paper, and placing on it keys, a glove buttoner, etc. Then this plate was exposed to the warm emanation of thorium, and the accompanying photograph was obtained in one hour.

The photographs that accompany this article—thoriographs I have called them—were produced by various methods and with varying degrees of exposure. The data concerning them will be found under each cut.

Prof. Ernest Rutherford of McGill University

Fig. 2. Thoriograph taken in a dark closet by an oxide of thorium screen. Time of exposure, 48 hours.

was among the first to investigate the properties of thorium. His researches in this field have done more, perhaps, than has been effected by anyone else toward solving some of the mysteries of this remarkable radioactive substance. In 1900 he discovered that thorium gave off an inert and highly radioactive gas, which he termed an "emanation." It diffuses through gases, liquids, and even through porous substances. Rutherford considers the emanation to be the result of successive chemical changes in the thorium. By chemical action the thorium atom produces a substance which he calls thorium X, and by a further chemical change, this thorium X produces the emanation. The emanation expels from itself a negatively charged body, which constitutes the Becquerel rays. These rays are the same as those produced by radium, polonium, actinium, and uranium.

It has been recently proved by scientists who

Fig. 3. Thoriograph taken with the emanations of hot thorium oxide. Time of exposure, 1 hour.

have experimented with thorium that its radioactivity and emanations are antiseptic, antifermentative, and inimical to germ life. In conjunction with Hugo Lieber, we have shown that grape juice, when exposed to radioactive matter, will not ferment for a month, even though it is kept in a warm room, with the bottle uncorked. In other experiments the oils of juniper and erigeron were used. These oils ferment and decompose in a few days if left exposed to the light. But after treatment with thorium emanations, even in the presence of light, they nevertheless were preserved in their original state for several weeks.

The antifermentative property of thorium emanations is further shown by the following experiment: Two bottles were taken, each containing agar-agar, starch, and mold (such as may be obtained from fermenting fruit). The contents of one of these bottles were subjected to the radioactive emanations of thorium, and those of the other were not. In the first bottle the growth of the mold was greatly inhibited, whereas, in the second bottle, the mold grew abundantly and soon filled the bottle. From these observations it is evident that thorium has a marked effect on microorganisms and fermentation, a fact suggestive of a vast field of usefulness in medicine.

The radioactivity emanates from thorium in every form, whether in powder, solution, paste, or ointment. The best results, however, are likely to be obtained from the gaseous emanations when used as an inhalation. This form of emanation may be obtained, either by making a solution of thorium nitrate, or, better still, by heating the oxide in a glass

receptacle, on a sand bath. For external application thorium may be made into a paste or a 25-per-cent. ointment, and used as an antiseptic in chronic skin diseases, particularly those of parasitic origin.

Thorium in Tuberculosis.—Dr. Soddy of London and Professor Rutherford of Montreal have suggested the use of thorium inhalations for tuberculosis. Certainly, from its antiseptic and antifermentative actions, it would appear to be a desirable agent to apply directly to the tissues affected in the fight against the tubercle bacillus.

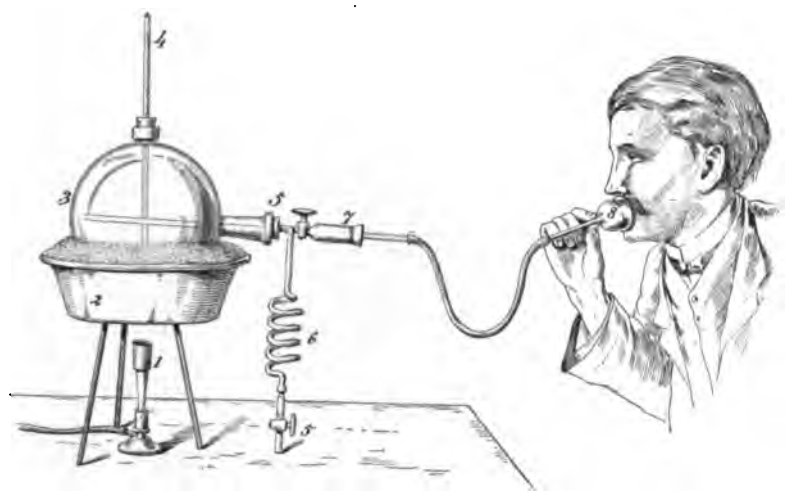

FIG. 4. Lieber's apparatus for thorium inhalations. 1. Bunsen burner. 2. Tin vessel containing white sand. 3. Glass vessel containing thorium oxide. 4. Thermometer. 5. Inlet for air. 6. Spiral glass-tube to prevent escape of emanations. 7. Outlet for emanations 8. Mouthpiece for inhalations.

As I have previously stated, there are two methods of obtaining these radioactive emanations, for use in the treatment of tuberculosis. One method is to use a saturated solution of nitrate of thorium in a large shallow receptacle. The larger the area of the vessel, the greater the amount of the emanations. A slight current of air can be caused to pass over the solution from a compressed air tank, while the patient is inhaling. With the nitrate of thorium there may be more or less free nitric acid; this must be neutralized by passing the emanations, before inhalation, through a wash-bottle containing a saturated solution of sodium bicarbonate.

The other, and by far the best, way of obtaining the emanations, is by heating the oxide of thorium. The apparatus I am using for this method of inhalation is the invention of Hugo Lieber. The accompanying cut shows the various parts of the apparatus, and the method of administering the thorium emanation.

The radioactivity of thorium is many thousand times less than that of pure radium, but thorium is also many thousand times cheaper ($7 a pound), and it can be used for a longer period of time at each treatment, thus making up by the increased duration of the treatment what it lacks in potency.

Rutherford states that "when thorium nitrate is changed into an oxide by heat, it temporarily loses its radioactivity. However, when it is exposed to the air it soon begins to regain its activity. In four days it is one and a half times more active, in twelve days, two and a half times; and at the end of two weeks it reaches its maximum radioactivity, which is four times as great as was the original nitrate of thorium."

In using Lieber's thorium apparatus, the inhalation of the emanations leaves in the lung cells a fine film of radioactive matter, which, in turn, produces the phenomenon of induced radioactivity in the same parts. This "induced" radioactivity will remain in the air-cells long after the original emanations have been exhaled. In most cases it lasts for from one to two days, after which it gradually disappears. In this connection it is interesting to observe that the radioactivity of thorium can be proved, even after it has entered the lungs. If a patient inhales the thorium emanations, and then, while in a dark room, exhales, allowing the breath to come in contact with a photographic plate, the exhalation affects, and partly decomposes, the silver salts on the plate.

As the induced radioactivity of the thorium emanations lasts from twenty-four to forty-eight hours, this acts as a guide to indicate the proper frequency for the treatments. An inhalation given every day or every other day would keep the lung cells constantly in a radioactive and antiseptic condition. While the thermometer in the Lieber apparatus should indicate a temperature of from 250° to 300°F., the emanations are partly cooled by passing through the glass and rubber tubing, and may not be much above the normal body temperature at the moment of inhalation. These inhalations may be taken for a period of fifteen minutes at the outset, which period may be gradually increased to half an hour.

This method of treating tuberculosis will not interfere with other measures, such as dietetic, hygienic, and even drug treatment.

240 WEST ONE HUNDRED AND SECOND STREET.

A NEW AND SIMPLE PHOTOTHERAPEUTIC LAMP.*

BY HENRY G. PIFFARD, M.D., LL.D.,
NEW YORK.
EMERITUS PROFESSOR OF DERMATOLOGY, NEW YORK UNIVERSITY; CONSULTING SURGEON CITY HOSPITAL; FELLOW OF THE NEW YORK ACADEMY OF SCIENCES, ETC.

THE fact that sundry luminous and non-luminous radiations can be utilized in the treatment of certain pathological conditions is now so well known that any testimony I might personally give would be superfluous.

The real question that at present concerns us is simply one of technique. If the sun's rays are to be utilized, we have the choice of the earlier method of Finsen of Copenhagen, who gave exposures of moderate intensity for an hour or more daily, and continued for weeks or months; or we may adopt the more radical method of Thayer of San Francisco (*Pacific Medical Journal*, April, 1902, and September, 1903), who uses concentrated rays of such intensity that the parts are not simply scorched, but actually carbonized, and the morbid tissues destroyed in many cases at a single sitting. Finsen soon found that he could not command the sun, and adopted the electric arc as a substitute. We in New York and in the more northern portions of the continent find the sun undependable, and are therefore forced to rely on electricity to supply the radiations we desire to employ.

Finsen's standard outfit comprises a large arc-lamp with carbon electrodes and consumes electric energy equivalent to more than ten horse-power, if run on the usual 110-volt circuit. Connected therewith are four optical bodies, furnished with quartz lenses and chambers and tubes, for the circulation of water. In addition there is a set of quartz compressors used for squeezing the blood out of the part to which the rays are directed. With this installa-

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, January 8, 1904.

tion four patients can be treated simultaneously, to each of whom is assigned an attendant whose duty it is to manage the compressors. The seance usually lasts for an hour, and in many, if not most cases, is repeated daily for from three to six months, according to the nature, extent, and severity of the lesions that are present.

More recently a simpler installation, known as the Finsen-Reyn lamp, is also manufactured at Copenhagen under the auspices and with the approbation of Finsen. It differs from the older form by possessing but one optical body, much shorter than the one in the original construction. It consumes but one-fourth of the current required by the larger lamp, and can be used by but one patient at a time. It is furnished with a set of compressors, which, when used, require the services of an attendant. This lamp is fully as efficient as the larger one, as, owing to the greater proximity of the patient to the arc, the luminous energy at the point of application is the same, at least so says the advertisement.*

Such, in brief outline, is the Finsen method of treating lupus and some other cutaneous affections.†

It will be readily admitted, I presume, that the surgeon's success with photo- or actinotherapy will depend somewhat on his knowledge of the physical factors connected with agent he employs. Judging from the statements found in many of the published articles that are almost daily encountered, I am forced to the conclusion that some at least who are using phototherapy are deficient in the very knowledge that should be the foundation on which they should build their hopes of success.

The sun radiates its energy in all directions, and the portion that reaches our earth comes to us in the form of wavelets, varying in velocity and in length. Those of longest wave-length are invisible and inappreciable by either of our organs of special sense, but become known to us by their warmth; others of shorter wave-length become known to us through the organs of vision, and we speak of them as light. When duly mingled in their natural proportion this light is white, but if analyzed with a prism we find that this white light is not homogeneous, but is composed of radiations of varied wave-length and varied color. Each wavelength doubtless possesses its own color, but as the differences are so minute it has been found convenient to group them into six divisions as red, orange, yellow, green, blue, and violet. These alone should be spoken of as light.‡ Beyond these again there are other wavelets of still shorter length. Their chief characteristic is the readiness with which they induce certain chemical changes and also give rise to the phenomena of *fluorescence* and *phosphorescence*. These various radiations taken collectively constitute the spectrum, which may be conveniently divided into three portions: (1) the so-called heat rays *below* the red known as the *infra-red;* (2) the luminous portion or light; and (3) the portion *beyond* the violet, known as the *ultra-violet.** Our chief concern at present is with the blue and violet portions of the visible spectrum, and with the ultraviolet invisible radiations. In sunlight we have but a minimum proportion of ultraviolet as compared with some other luminous sources, and we are therefore obliged to look to artificial light for a richer source of the latter. In the ordinary arc light with carbon terminals there is a much larger proportion of ultraviolet than in sunlight, and if we substitute iron for carbon the proportion is still further increased. As already stated, Finsen uses the arc with carbon terminals, but Dr. Sophus Bang of Copenhagen, connected with Finsen's institute, devised a lamp with iron erminals, providing a water circulation to keep them cool.†

The condenser spark, however, is still richer in ultraviolet radiations, and Goerl of Nürnberg availed himself of this fact in the construction of a convenient little lamp, which, however, requires for its operation a static machine or an *x*-ray coil furnished with a condensor in the secondary eircuit.‡

Numerous modifications of the Finsen, the Bang, and the Görl lamp have been made, the desire being to produce a lamp of simpler and less expensive construction without any great sacrifice of pediency. About a year ago the present writer devised a condenser spark lamp in imitation of that of Görl, which is here shown (Fig. 1) and which has given him great personal satisfaction, and which he believes has proved satisfactory to others who have used it. It is more particularly described in the MEDICAL RECORD of March 7, 1903.

FIG. 1. The author's spark-gap lamp for ultraviolet rays (to be used with static machine or coil).

A number of lamps of the Bang type—that is, with iron terminals hollowed out to permit the circulation of water—have been devised, and one of French construction particulary attracted my attention.¶ One of these was sent for, but a lamp of slightly different construction was furnished, and on trial was found impracticable and unsatisfactory, and was, in fact, a lamp that no American manufacturer, jealous of his reputation, would think of placing on the market. I made no clinical use of the lamp, but testing it experimentally was impressed with the danger of accident in case either of the terminals should become perforated. Iron like carbon terminals are rapidly consumed in the electric arc, and if one of them should burn through, the water would spurt out upon the patient—an unpleasant, though probably not serious, accident.

Desiring to test the comparative therapeutic value of the Spark-gap radiations with those derived from the low-tension arc, my recent efforts have been to produce a lamp that would be free from

*"Der Apparat bietet durch seine grosse nähe der Lichtquelle und durch die schräge Stellung der Kohlen ungefähr diesselbe Lichtmenge wie die grossen Apparate."

†It is to be regretted that thus far Finsen has vouchsafed but little information concerning the minor details of his technique, and the purchaser of the apparatus must exercise his own ingenuity in applying the means at his command to the ends he desires to accomplish.

‡"LIGHT.—The form of radiant energy that acts on the retina of the eye and renders visible the objects from which it comes; the illumination or radiance that is apprehended by the sense of vision. . . . According to the *undulatory* theory, now generally received, radiant energy is propagated in waves that vary in length, and only those that effect the eye are known as *light*."—Standard Dictionary.

*It must be borne in mind that the infra-red and also the luminous portion possess actinic properties, though less in degree than the ultraviolet, and this latter exhibit, thermal properties, though less in degree than the others.

¶*Archives d'Électricité Médicale*, March 15, 1902.

the objections mentioned, and at the same time be of simple construction and convenient of manipulation.

The result is here shown.

FIG. 2. The author's hand arc-lamp.

I need not detail the problems that confronted me at nearly every turn, and it was only through the courtesy of the Waite & Bartlett Manufacturing Company that I succeeded in bringing about the result that I sought to accomplish. This firm kindly permitted me to oversee this work at their factory, and placed at my disposal an exceedingly competent mechanic.

Briefly described, the lamp has the general outward form shown in the illustration. The terminals are of iron and solid, and by giving free ventilation I am enabled to dispense with the water tubes. One of the terminals is fixed, and to this I prefer to attach the cord carrying the positive current. The other is movable, and by means of an adjustable spring is maintained at a proper arc-ing distance. The lamp may be attached, with proper resistance in series, to any outlet connected with a commercial 110 volt D. C. circuit. The fuse wire connected to the outlet on the wall should be capable of carrying at least six amperes.

The conducting cords with the rheostat in series are furnished at one end with an attaching plug and at the other with sockets for connecting the lamp. The cords should be insulated with asbestos and not with rubber or gutta percha. When the lamp is to be used I strongly recommend that it be first connected with the cords, and the cords afterward connected with the desired part of the house service. The current should now be turned on at socket. To produce the arc the push button on the handle is moved forward until the terminals are in contact, and then brought gently back to permit the arc to form. The arc may be broken at any moment by simply blowing it out as one would blow out a candle, and this should always be done *before* turning off the current at the wall socket. The tube that projects from the front of the lamp carries a quartz plate, and is left purposely open at the sides to permit a free circulation of air.† The strong actinic light escaping from the sides of the tube will naturally impinge on and effect the neighboring parts unless they are properly protected. This may be readily accomplished by means of a shield of non-actinic paper. They should be about three and a half inches in diameter with a central aperture of one and a half inches and may be slipped over the tube before it is attached to the front of the lamp. Should the skin lesion be quite small, a suitable diaphragm can be readily made out of the small paper disk, that is cut from the center of the larger one.

The entire outfit, including the rheostat, weighs about eight pounds, and may therefore be easily carried to the clinic or the house of a patient, if necessary.

The lamp here described, in common with the Bang lamp, furnishes radiations that are comparatively richer in ultraviolet than the Finsen and its numerous imitations. In this respect, however, they are inferior to the radiations from the spark lamp.

It must be remembered that no matter what phototherapic lamp is used the part to be operated on must be deprived so far as possible of its circulating blood. This may be accomplished by compression as employed by Finsen, or better and more conveniently, I believe, by the cataphoric introduction of adrenalin as originally proposed by myself (MEDICAL RECORD *loc. cit.*). I use a solution of chloride of adrenalin, 1-1000, and in hundreds of applications have found it efficient and free from any inconvenience or misadventure. In a few instances recently I have added the di-hydrochlorate of quinine to the adrenalin solution. This addition does not appear to impair the desanguinating property of the adrenalin, but I am not at the moment prepared to say that any actual therapeutic advantage accrues from this addition. This can only be determined by further experiment.

256 WEST FIFTY-SEVENTH STREET.

†The lamp may be furnished in addition with a *quartz* lens, which, mounted in a suitable adapter, will furnish at will either parallel or converging rays.

EARLY OPERATIONS IN ABDOMINAL TROUBLES.*

BY EDMUND M. POND, M.D.,
RUTLAND, VT.
SURGEON TO THE RUTLAND HOSPITAL; CONSULTING SURGEON TO THE PROCTOR HOSPITAL.

THE remarks I am about to make do not apply to all physicians, for the majority of men doing general practice are keen to make early diagnosis and prompt to call surgical aid. Still there are many who do not make their diagnosis early and do not call surgical aid until the case is almost beyond human help. If you wish to be conservative, you must be prompt in diagnosis and early in operation. The general practitioner is sometimes apt to consider lightly surgical cases, saying, "I always call a surgeon for such work," and I will add, "often too late." The high mortality in abdominal troubles does not come from the operation, but from the delay in having it performed. How can you have an early operation unless you can make your diagnosis? How can you diagnose unless you are perfectly familiar with surgical cases? How can a surgeon diagnose unless he is equally familiar with medical cases?

I dare say there is not a man present but who can recall certain patients who would be alive to-day had there not been delay. Of course, delay comes often from the family, but the majority of the laity to-day appreciate the dangers of late operation and will censure not only the surgeon who "kills the patient," but also the family physician who

*President's annual address before Vermont State Medical Society, Bellows Falls, Vt., October 15, 1903.

waited too long. To help things along and smooth them over, the newspapers add "so-and-so dies as the result of an operation," thus adding still more discredit to late surgical work. What should be the attitude of the surgeon to the general practitioner? Here is a common case: A patient is taken suddenly ill with appendicitis, and the diagnosis is not made. To allay pain, an opiate is administered, and this repeated as required. In the morning the patient seems a little better, but still a diagnosis is not made, or the physician waits another day before calling a surgeon. The following day the patient is much worse, and the surgeon is called; he finds the patient with a rapid pulse, leaky skin, and a hard abdomen. Operation reveals the general peritoneal cavity, and system in general infected. There is profound collapse at the end of the operation, and the patient rapidly sinks, and dies, or, after a hard struggle full of pain and suffering, he makes a slow, tedious, and imperfect recovery. Immediately after the operation the friends talk to the surgeon about this way: What are the chances? How do you find him? Was the operation early enough? Would it have been better if performed two days ago? Now, in the cited case, I ask was the operation early? Can the surgeon say to the family: "Yes, the operation was early, still there is no hope?" Can he risk his reputation, and try to convey to the family that it was in time, when he knows, as do also the family, that it was too late. No, he cannot do that; he must say: "The earlier the operation, the better are the chances." Such cases bring discredit to the surgeons, but they hurt the general practitioner far more. The laity expect that their family physician will protect them; that he will, if necessary, call a surgeon, and call him promptly, and if he does not, they will blame him. The surgeon is often called to operate upon delayed cases that are almost sure to die. Shall he operate? A very eminent surgeon said to me when we were discussing these cases, "I do not operate upon them, I simply say that it is too late." There is truth in this, still there are cases that seem almost hopeless in which recovery does occur. For this reason I think if the family desire an operation, after fully understanding the situation, they should have their wish gratified. I do not, however, think the surgeon should shield the general practitioner to the extent of making statements that are untrue. If the general practitioner delays, he should assume the responsibility.

What do we mean by early operation? Is it twenty-four hours, or three days? As I mean it, there is no stated time; in one case twelve hours is late, in another case three days is early, depending entirely upon the condition. Among the cases demanding earliest operation, are those of perforation of the stomach, intestines, appendix, or gall-bladder. In stomach perforations there is often a history of gastric ulcer or gastric disturbance. I was called at noon to see a young man of about twenty-five years, a carpenter by trade. While working, he was suddenly taken with severe epigastric pain and collapse; the pulse was very rapid, the respiration catchy, and the face anxious, the abdominal muscles were tense, especially in the epigastric region, and tenderness was present in the same region; but a little to the left of the median line there was loss of liver dulness. A diagnosis of perforating gastric ulcer was made, and he was urged to go to the hospital, only a block distant, and have an operation as soon as the first shock was over. He flatly refused, even after the consequences were explained to him. He continued to get worse, and the next morning his condition was hopeless. The family then requested an operation, and this was acceded to, but no hope was offered. When the abdomen was opened it was found filled with stomach contents and sero-pus. A perforation was found in the posterior wall of the stomach. This was closed and the abdomen was flushed and drained. The patient died twenty-four hours later. Very similar to this is the following: A servant girl after a hearty evening meal, was taken with severe pain, vomiting, and collapse; she was stimulated and made comfortable during the night. I saw her early in the morning in the following condition: the pulse and respiration were very rapid, the temperature was subnormal, the abdomen hard, distended, and tender. There was a loss of liver dulness, the face was anxious and the eyes were sunken. A diagnosis was made of stomach perforation, and little hope was offered. Operation revealed a large ulcer; this was sutured, and a large amount of stomach contents and sero-pus was washed out of the abdomen; drainage was used. She died a few hours after the operation—that is, twenty hours from the onset of symptoms. In this case fourteen hours was late. If you had a stab or gun-shot wound of the stomach you would not wait fourteen hours, then why wait in a similar condition due to ulceration? It is surprising how rapidly infection follows perforation, and what a large amount of pus can form in a short time. A man of about thirty-eight years, a draftsman, had worked hard all day, and was as well as usual. After eating his supper, he was taken with severe pain in the abdomen and collapse. Morphine and stimulants were used. I saw him the following day at noon, fourteen hours after the onset. The pulse and respiration were very rapid, the face was anxious, the eyes sunken, and the body bathed in perspiration; the abdomen was distended, tender, and very hard. Liver dulness was absent. Gastric perforation was diagnosed, and the prognosis was death with or without operation. Operation was, however, requested. The gas in the peritoneal cavity was under such pressure that when the abdomen was opened, there was a distinct sound of explosion and pus spurted in every direction. In this case there were quarts of what appeared pure, yellow pus; of course, some of it was stomach contents. The intestines were fiery red and covered with patches of white lymph. The abdomen was flushed and drained, but the patient died a few hours after. This was a late operation. Intestinal perforations give very much the same history. A laboring man of middle age was taken while at work with pain and collapse. The pain was located over the appendix. I saw him twenty-four hours later. Collapse was marked; the abdomen was enormously distended, tender, and boardy; the pulse was over 150. Operation was not advised. The symptoms were those of a large perforation of the appendix, and the location favored the diagnosis. Autopsy showed a small (typhoid) perforation of the ileum.

Another misdirected idea is that of interval operation for appendicitis. Of course, the patients that get well and are afterward operated upon in the interval give a very small death rate, but when you add to this those that die during the attacks while waiting, you have a much higher mortality than if you established the rule to operate in every case as soon as the diagnosis was made, and made the diagnosis early. Interval operations in a large hospital, or where the patient can be watched by experienced diagnosticians and trained nurses, may do, but for the country practitioner, they are dangerous, and he will lose more patients than if he adopted the other rule.

I have seen so many lives lost by the waiting idea, that I am firmly convinced that every patient should be operated upon as soon as possible after the diagnosis is made. Some years ago, I was summoned one night to see in consultation and operate upon, if necessary, a young lad of about twelve years. There was some discussion between the council, and part were opposed to operation, advising "to wait for an interval operation." It was a typical case of suppurative appendicitis with general peritonitis. I cite it simply to show that many good practitioners do not grasp the full understanding of interval operations, and I again emphasize that it is safer for them to adopt the rule to operate in all cases as soon as the diagnosis is made. To return to our case, upon opening the abdomen, pus was present everywhere. A gangrenous appendix was found resting on a coil of small intestines. It was so septic that where it came in contact with the intestines it had produced gangrene. About eight inches of intestines were black and gangrenous. A foot of small intestines was resected, and the ends stitched to the abdominal wound. The abdomen was flushed and drained, and the intestine was irrigated, and filled with saline solution and brandy. The patient recovered. Three months later the ends of the intestines were freshened and joined by a Murphy button. The boy is now perfectly well. This is an unusual condition. I have many times seen small areas gangrenous from contact of a septic appendix, but never before eight inches absolutely gangrenous throughout its entire thickness. You will all admit that the operation was late, and that it was not a suitable case for an interval operation.

It is not always possible to make a positive diagnosis at once, but you can take your symptoms, and by grouping and by exclusion you can soon decide the question: Is it safe to wait, or must the operation be done at once, regardless of the diagnosis? I saw a boy of ten who was taken suddenly sick with a pain in his abdomen. There was tenderness over the appendix and the abdomen was distended. The muscles were rigid, but not hard. The temperature, pulse, and respiration were all considerably elevated. It appeared like a well-marked case of appendicitis, except the muscular rigidity. Cough, however, was present that excited suspicion of pulmonary trouble, but examination of the lungs was negative. The following day the cough was more severe; an examination of the lungs showed pneumonia of the lower right lung. In this case it was twenty-four hours before appendicitis could be excluded and pneumonia diagnosed. Other chest complications may simulate abdominal trouble, and must be borne in mind.

In abdominal troubles there are certain symptoms common to all, varying somewhat according to the lesion and its severity. Pain, tenderness, and muscular rigidity are present in almost all cases. Pain indicates a lesion. Tenderness tells where it is, and muscular rigidity shows nature's effort to protect the diseased areas. This combination always indicates trouble that should be watched with care. If over the appendix it is pathognomonic of appendicitis, and here you must remember that the appendix is not always in the same location; the left iliac, the right lumbar region, or the pelvis may be occupied by this uncertain organ. If the pain is over the gall-bladder, it is equally significant of gall-bladder disease; if over the stomach, it may mean gastric ulcer; if it is in the lower abdomen, just above the pubes or to one side, it is suspicious of tubal or ovarian disease. In the last named, a vaginal examination will often decide the diagnosis. A servant in my home, a young girl of eighteen, was apparently well; she had had two slight attacks of colic lasting only about a quarter of an hour, after which she was well as usual. One day when doing her usual work, she was taken with severe pain in the epigastric region and collapse. Morphine and stimulants were given, and it looked as though she would die at once. The pain was agonizing; the muscles over the abdomen were rigid, especially the right rectus in its upper half, and tenderness was most marked here. From the character of the symptoms, I thought at once of perforation, probably of a gastric or intestinal ulcer, or of an appendix pointing upward and unusually high. Liver dulness was present, showing that there could not be much gas in the peritoneal cavity. While the symptoms were those of a perforation, the gall-bladder could not be excluded, as we had pain, localized tenderness, and muscular rigidity over a point midway between the navel and lower costal cartilages of the right ribs. There were the sudden and severe onset, collapse, a pulse of 140, and a temperature in a few hours of 105°; an anxious facial expression, and sunken eyes, rapid respiration, tympanitis, and constipation. The diagnosis was between an abnormally high located appendix that had perforated, a perforated gastric ulcer, or gall-bladder disease. There was no history to aid, no jaundice, no vomiting of blood, or stomach disturbance, no previous attacks of appendicitis or of uterine disease. The grouping of the symptoms left no doubt regarding the advisability of an operation. This was proposed and refused. For two days she improved, then suddenly became worse. She then consented to an operation. Upon opening the abdomen, a mass of adhesions was found. Upon breaking these up, a large tense gall-bladder appeared with a perforation in its posterior wall, this was covered by an adhesion of omentum. Upon opening the gall-bladder about fifty stones and a few ounces of pus were found. The largest stone was about the size of a large walnut. The gall-bladder was emptied and stitched to the incision and the abdomen drained. The patient made a good recovery. The collapse evidently took place at the time the perforation occurred.

Another gall-bladder case of interest, from its rarity, is the following: A man of sixty-five was taken with an ordinary typical attack of gall-bladder inflammation, pain and localized tenderness were present over the gall-bladder, very marked muscular rigidity over the entire abdomen; the abdomen was like a board, but not much distended. He had been sick nearly a week, his temperature and pulse were running up, and an operation had been urged. He did not look, however, very sick. Upon opening the abdomen it was found full of bile and seropus, and all the intestines were red and covered by lymph the gall-bladder was gangrenous, gray, green in color, and perforated in many places. On removing the diseased parts, the gall-bladder was found to be so rotten that it was picked away with the fingers up to the common duct. It looked like a hopeless case. The abdomen was washed out, large strips of gauze were carried in various directions, and the wound was left open. Collapse was marked. The man, however, made a good recovery, and is now working hard each day. There are two things about this case. First, Mayo Robinson says that there is only one case on record of total gangrene of the gall-bladder and that case ended fatally. Second, the extreme muscular rigidity was the symptom of warning and when present generally means severe trouble.

Intestinal obstructions always demand prompt action; here hours count. Two symptoms are most pronounced, constipation and vomiting; these are also common in sepsis, but certain symptoms will

always aid you in making an early diagnosis. These cases generally hold up until the last, and then go to pieces in a hurry. A boy of ten was apparently well Saturday. The evening of that day, he was taken with colicky pain and vomiting; the bowels were constipated. He had had an attack like this about a year before, and it was a week before the bowels could be moved. Sunday the vomiting and pain continued, still the bowels could not be moved. I saw the patient Monday morning, thirty-six hours after the onset. The vomiting was regurgitant in character, brown and offensive with fecal odor. The abdomen was distended and tender; the face pinched, eyes sunken, pulse rapid and thready, respiration accelerated. The diagnosis was intestinal obstruction, and little hope was offered. He had failed very rapidly in a few hours. Operation was asked for by his parents. Upon opening the abdomen there was a gush of brown, offensive serum. Distended and collapsed intestines were soon found that led to a strangulation by a band caused by an old appendicitis. Several feet of intestines were found strangulated and gangrenous. An artificial anus was made. The boy died a few hours later—thirty-six hours after the onset—but too late for such a condition. In this case there was a history of a previous attack, and a recovery without operation. Because a patient has recovered once, twice, or more times from sim ilar attacks, it is no sign that he will recover from the next, and you must not be misled or influenced by such a history.

Floating kidney sometimes give rise to severe symptoms, and as this is a very common condition, it should be borne in mind in making a diagnosis. A young woman of thirty-five was operated upon by me five years ago for acute appendicitis. At the time of the operation an ovarian cyst was found and removed. She made a good recovery. A year later she began to have pain in the epigastric region, tenderness, vomiting, and some fever. These attacks increased in frequency. Examination showed a freely movable kidney which, when displaced, occupied about the region of the gall-bladder, but nearer the umbilicus. Some jaundice was present. She was running down, the fever was getting higher with each attack, and the pain, tenderness, and muscular rigidity were becoming greater over the right hypochondriac region. The urine contained hyaline casts, but aside from this was normal. Operation was advised. An incision through the upper right rectus muscle showed a mass of adhesions, a very large liver, and a distended gall-bladder. Pressure in the back threw the right kidney into the wound. The gall-bladder was opened and stitched to the wound. An incision was next made in the back, and the kidney, partially stripped of its capsule, was anchored, the wound being left open. The kidney was very soft and friable. This case was of interest because it so closely simulated gall-bladder disease, and, in fact, an eminent physician had diagnosed it as such, excluding floating kidney. Cases giving such a history should be operated upon early, not put off from year to year until the kidney is destroyed and the other organs injured by pressure. Gall-bladder cases give such good results that they should be classed among cases demanding early operation. There is no excuse for allowing a patient to go through life with gallstones that are giving trouble every little while. If they don't give trouble, they may be left alone.

The pelvic diseases demanding operation are many; operation in these cases is, as a rule, delayed too long, especially in the septic cases. We will pass by them, however, and consider a condition formerly thought rare, but now known to be common—that is, extrauterine pregnancy. I was called to see a case thought to be one of appendicitis. The woman had been sick about a week with tearing pains in the abdomen, associated with some collapse and tenderness and muscular rigidity over the lower abdomen. Examination showed the cul-de-sac occupied by a pulsating and fluctuating mass. There was a history of delayed menstruation and irregular flowing; also of stomach and breast disturbances. Operation showed a mass of adhesions and blood-clots in the abdomen. After these adhesions had been broken up, an abdominal pregnancy was revealed. A full four months' fœtus was quickly removed with the placenta and cord. Hemorrhage was terrific, and controlled only by compression of the abdominal aorta and a firm compress of iodoform gauze filling the pelvis. A good recovery followed. Such patients are in the greatest danger, for a fatal hemorrhage may occur at any moment. I was called a short time ago to see a young woman who thought she had miscarriage. She had run over her period two weeks, was nauseated, and had breast symptoms; the flow started freely, and considerable pain was present. She had been flowing over a week, and the pains were more severe; a little elevation of temperature was present. I curetted considerable material from the uterus. Bimanual examination revealed a retroverted uterus, with prolapsed tubes and ovaries, one tube being somewhat enlarged. There was a history of two severe attacks of appendicitis, several years before. The patient improved for a week, when the flow returned and the pains increased in severity, being of a tearing character. A few days later another examination was made and the tube was found somewhat larger. A diagnosis of tubal pregnancy was made, and an operation was performed the following morning. Free blood, old clots, and serum were present in the abdomen, to say nothing of adhesions. After a while, a pregnant right tube was found and removed. The appendix was adherent to it. The tube had not ruptured, but hemorrhage had taken place from the fimbriated end. The woman is now making a perfect recovery. These patients must be operated upon early, otherwise a great many will die, or, if they do not die, will have a long severe sickness before they recover, and the recovery may be only partial. You must consider that most of my reported cases have been severe ones. I could report many simple, mild cases that turned out to be equally severe, simply from waiting. Always treat a mild case promptly and carefully, and each year you will have less severe ones.

In closing, let me simply say, if you wish to do right by your patients who put their utmost confidence in you, diagnose and operate early. If you wish to be conservative and have a small death rate, diagnose and operate early. If you wish to be up to date and have the respect of the medical profession, and help its cause along, diagnose and operate early.

Massage in the Treatment of Fractures and Sprains.—According to Eisendraht, the contraindications to the use of early massage in fractures or sprains are the following: (1) Tendency to displacement of fractures in fractures. Under such conditions it is best not to begin either massage or movements until the union is firm (fourth to fifth week). (2) In compound fractures until the wound is healed. (3) Wherever the condition of the skin is such as to permit of infection; for example, the presence of blebs, or extensive abrasions. (4) The presence of fragments which project but do not penetrate the skin.—*Chicago Medical Recorder.*

TWO CASES OF ABDOMINAL TRAUMATISM.*

By A. B. ATHERTON, M.D. LL.D.
FREDERICTON, N. B.

CASE I.—M. K., aged forty-eight years, farmer, French-Canadian. At 2 P.M., on June 2, 1901, while he was endeavoring to discharge an old loaded musket it hung fire. On lowering it to examine the cap the gun went off, the butt end striking with great force against the right side of the abdomen. He suffered much pain at once and had some vomiting. Owing to unavoidable delay in sending into town for a doctor, I did not visit him till 10.30 P.M. I found him still having severe pain in the belly, but not apparently suffering much from shock. His pulse was 88. The abdominal walls were hard and tender, but there was no distension.

I at one administered ½ gr. of morphine hypodermically, and then made arrangements for his immediate removal from his home to the hospital in Fredericton, a distance of ten miles. He was placed on a bed in an ordinary express wagon and conveyed to the city over a rough road, the journey occupying about four hours. He suffered considerably from the jolting on the way, and required ½ gr. or more of morphine to keep him at all comfortable. On arrival I found the pulse about 100, and the abdomen below the navel somewhat distended. The muscular rigidity still continued. Respiration thoracic.

After a hasty preparation, I operated at 6 A.M. A short incision was made below the umbilicus, which was subsequently enlarged to six or seven inches. Some turbid serum first ran out. Then the omentum and several coils of inflamed and distended bowel presented themselves to view, all more or less matted together with fresh lymph. I had to allow a number of coils to escape before I found the ruptured one lying to right side and having a ragged opening extending at least two-thirds across it; a good deal of its contents was extravasated in the neighborhood, consisting of a thin, yellowish fluid. After isolating the injured portion by means of sterilized gauze pads, I trimmed off the torn edges of the tear, and united them with two rows of silk sutures. Then the abdominal cavity was well washed out with warm boiled water, and a larger rubber drainage tube and a strip of iodoform gauze placed in pelvis. A second strip of gauze passed back into the lumbar region and another down in the direction of sutured gut. The abdominal wound was then closed with through-and-through silk-worm gut sutures, leaving, of course, openings for the rubber and gauze drains. The usual antiseptic dressings applied, with broad bandage over all.

During and after operation he showed signs of quite serious collapse, for which he received $\frac{1}{20}$ gr. of strychnine hypodermically, and a saline transfusion of 30 oz. This rallied him for a time, but by 10 A.M. his pulse became very feeble again, beating at 132. I now gave another $\frac{1}{20}$ gr. of strychnine under the skin and an enema of alcohol (½ oz.) in warm water (10 oz.) At noon the pulse had fallen to 120, but it was still very weak. A third dose of the strychnine given as before. The wound also redressed, as there had been a free discharge of blood-stained serous fluid.

At 5.30 P.M. the pulse was 108 and stronger. His countenance looked better also. A fourth dose of strychnine had been given at three o'clock. Dressing changed.

10 P.M.—Had ½ oz. of alcohol in 10 oz. of warm water by rectum two hours ago. Pulse, 100; temperature, 99°. Dressing changed

June 4. 9 A.M.: Slept about two hours. No opiate since operation. No vomiting. Has taken a few ounces of milk and lime water. Dressing changed every six hours, as discharge continued free. Pulse, 100; temperature, 98.6°.

As the large bowel was found pretty full of fæces at the time of operation I ordered 1 gr. of calomel every hour till 6 gr. were taken.

4 P.M.: Calomel caused vomiting. A large round worm brought up. Gas has passed. At 5 P.M. a good movement occurred.

June 5. 9 A.M.: Had quite severe pain in abdomen during the evening and night. About ½ gr. of morphine given altogether for it. Iodoform gauze and drainage tube removed from pelvis, and a smaller tube put in. Also, as the discharge was somewhat foul-smelling, I injected a mixture of peroxyde of hydrogen and water 1:3. Pulse, 80; temperature, 99.8°.

June 6. Considerable pain in back during night. Had ⅛ gr. of morphine; slept three or four hours. Pulse, 76; temperature 100.8°. Bowels moved by enema. Dressing changed every eight hours now; strips of gauze all removed; washed out with peroxyde of hydrogen again.

June 8. Skin adjoining the wound reddened for last two or three days. Also cut surfaces look somewhat sloughy. Complains at times of feeling "bad all over," and has had ⅛ gr. of morphine once or twice in twenty-four hours. Bowels rather loose; pulse, 80; temperature, 99.4°.

June 11. Doing fairly well. Pulse, 80; temperature, 100°. Both the wound in abdomen and the one made in the arm for transfusion are sloughy-looking. A coil of distended bowel inclined to protrude through the opening in the former. A silver wire suture put in to retain it in place.

Was very troublesome in night, and on two occasions got out of bed and wandered into another room. Is sensible when spoken to, but keeps up a moaning a good part of time.

June 12. For the last two days belly has been somewhat full and tender on right side, near anterior superior spinous process of ilium. Under cocaine I made an incision and let out nearly a pint of thin foul-smelling pus. The probe runs from this opening to loin. A rubber drainage tube eight inches long inserted.

June 15. Bowels continue rather loose. Abdomen flat. Takes food fairly well. Pulse, 84; temperature, 99°. Was very unruly last night, and tore off dressings and pulled out tubes. Quiet and civil enough in day-time, but becomes restless and quarrelsome when night comes on. Can scarcely be kept in bed then.

Chloroform given this morning and a drainage tube put through from loin to opening near anterior spinous process, its ends being tied together. The tube also replaced in pelvis. As the abdominal wound was being forced open by distended coils of gut, I put four or five silver wire sutures in.

June 20. Continues noisy at night. Often requires a dose of morphine to quiet him. Drainage tube removed from pelvis, as there was very little discharge from there.

June 21. On dressing wound this evening a considerable amount of fecal matter found in the discharge. The temperature has taken a sudden rise to-day, reaching 102.5°.

July 2. Doing fairly well. Has had a bad cold with cough and free expectoration for the last two weeks. Is taking iron and quinine. As the wire sutures had become loose I removed them. The

*Paper read at the Maritime Medical Association at St. John, N. B.

abdominal wound is quite open for three or four inches, a coil of adherent intestine filling up the gap.

July 12. Doing well. Belly flat. Less fecal matter discharged. Cough better. Pulse, 80; temperature about normal.

August 7. The discharge being slight, I removed the drainage tube.

August 14. As fecal matter can still be detected in the discharge, I put a very small rubber tube through from back to front again. The abdominal median wound about healed.

August 17. Allowed to have clothes on and be up out of bed for the first time. The discharge from drainage tube very slight.

In the afternoon he hailed a passing carriage and got on board for home.

On September 4 he presented himself at my office. He had taken out the small drainage tube a week before, and there has been only a very slight discharge since.

On October 5 he returned to hospital because of increased discharge. Fecal matter still found in it. A small tube put through from back to front again. He left for home on October 25, having the tube in.

On the 17th of April, 1902, he came to see me again. The tube had been out for some weeks. The opening in loin had closed, but a trace of fecal matter and thin pus still came from the anterior one. After trying pressure with pads and adhesive plaster for a month with only partial success. I finally cauterized the three-inch sinus which remained with nitrate of silver coated over a probe. After the slough thus produced had come away, renewed pressure, as before applied, was successful in permanently closing the sinus in two or three weeks.

Remarks: The result of operation for a rupture of the intestine depends very largely upon the time that has elapsed from the receipt of the injury. Generally speaking, the chances of recovery are fair when it is done within ten or twelve hours. After that length of time they become rapidly less, and in most cases death intervenes within thirty-six hours when nothing is done. In the case reported the abdomen was opened after sixteen hours had passed, and considering the fact of his having been during that time conveyed ten miles over a rough road in the dark, not to mention his subsequent refractory conduct. I think both the patient and operator may congratulate themselves that recovery took place, even after a rather long illness. It would have, of course, been better had I operated when I first saw him at his own home, but the surroundings were such that I dare not do so. Besides, I had no skilled person to assist me, and it was nighttime.

The small intestine is the part of the bowel generally torn in these cases, and the jejunum, ileum, and duodenum are the portions, in the order given, most frequently injured. I think from the character of the extravasated matter and the position of the torn coil, in this case the ileum was the seat of rupture.

The fecal fistula arose, I suspect, from the drainage tube. It did not form until eighteen days after the operation, and the character of the discharge was such as to lead me to think it came from the large intestine. The infection of the wounds arose doubtless from contact with the intestinal matter.

As to the diagnosis of rupture of the bowels, we may be pretty sure of it, if after a blow upon the abdomen there is agonizing pain with vomiting, associated with thoracic breathing and rigid tender abdominal walls. Shock may or may not be present. I once met with a case of nearly complete rupture of the duodenum from a kick of the boot, in which the man walked about half a mile after the injury. He was nevertheless dead in thirty-six hours.

When shock is marked just after the accident one should, of course, wait for it to pass off before operating, but there should be not an hour's unnecessary delay. The median incision will usually be chosen, unless the seat of the trouble can be clearly located to one side. We shall to some extent be guided to the injured coil by the greater amount of extravasated material and the inflammatory signs in its neighborhood. After closing the tear the peritoneal cavity must be thoroughly cleansed by mopping with gauze pads or irrigation, or by both.

The question of drainage is somewhat an important one, and is to be decided by the amount and character of the extravasated intestinal matter, and by the length of time this has lain in the peritoneal cavity and the consequent amount of mischief it has set up. When we are satisfied that everything of an offending nature can be removed by swabbing or irrigation, the abdominal wound should be at once completely closed. If doubts exist as to this, then drainage should be used either with strips of gauze or rubber tubes or with both. In the case reported I should have probably avoided the subsequent formation of the large abscess had I made an opening in the right loin at the outset and thus have secured through-and-through drainage.

Case II.—I was called by telephonic message from Dr. Wade of St. Andrews, N. B., on February 9 of this year, to go by train on the following day to see Wm. McQ., aged forty-five years, who had about noon, received a bullet wound from a small rifle of 22 caliber. The missile had entered the left loin about five inches from the spine and between the ninth and tenth ribs, lodging somewhere inside the abdomen. Within the first twelve hours the patient vomited about two quarts of blood. When I arrived at the farmhouse where he lived, twenty-seven hours had elapsed from the time the accident had occurred. I found him in fair condition, though somewhat weak. He had not much pain, though he had required about five grains of opium to relieve his sufferings before my visit. No vomiting for several hours. Pulse, 72; temperature, 99°. Not much distension or rigidity of abdomen.

After a consultation with Drs. Wade and Gove it was thought best to operate.

4 P.M.: Dr. Gove administered the anæsthetics ether and chloroform being used alternately. Dr Wade assisted me. One or two laymen had to be called in to hold the patient on the table, as he kept up an almost continual struggling from beginning to end of operation in spite of a very free use of the anæsthetics.

The abdominal incision extended from near the ensiform cartilage to the navel. As soon as the peritoneal cavity was opened, the intestine was forced out by the straining due to his struggling, which very much interfered with the different steps of the operation. A somewhat blackened opening was first observed near the inferior border of the cardiac end of the stomach. The peritoneal coat covered in the hole in the deeper coats, and had to be slit up a little so that I might place some through-and-through silk sutures in them. Afterward the peritoneal wound was closed by Lembert sutures of the same ma-

terial. I now noticed the bullet, of small size, entangled in the omentum and removed it. A bit of blackened omentum in the neighborhood ligatured and cut away. After a pretty long search, made longer by the patient's struggles, I found the posterior opening, about two and one-half inches from the anterior one, and treated it in the same way as I had the latter. As there had been no extravasation of either blood or gastric fluids, I then closed the abdominal wound with silk-worm gut sutures without drainage.

Pulse was 72 at the end of operation.

The after-treatment was carried out by Dr. Wade, to whom I am indebted for the following notes:

February 10. 6 A.M.: Pulse, 86; temperature, 100°. 4 P.M.: Pulse, 84; temperature, 99.8°.

February 11. 7 A.M.: Pulse, 84; temperature, 99.2°.

February 12. Had a natural movement of the bowels with some decomposed blood in it yesterday. Pulse and temperature normal to-day.

February 14. Bowels opened by enema. Some iced milk and lime-water allowed.

February 20. Sutures removed. Wound healed.

On February 22 solid food first given.

March 5. Patient is up and about the house.

Remarks: It may, perhaps, be questioned whether this man would not have recovered if no operation had been done. No extravasation of gastric contents had taken place, doubtless because of the small size of the wounds and their oblique direction, and it is quite possible that they might have closed without such escape having at any time occurred. Whether the presence of the bullet would ever have given trouble must, of course, remain doubtful. One's course should in a case of this kind be largely influenced by whether the medical man in immediate attendance on the patient is accustomed or not to abdominal surgery. If he is familiar with such work then the expectant method of treatment can be more safely followed. Seeing, however, that the hæmatemesis almost certainly proved that the stomach had been perforated, we felt we were justified in opening the abdomen at once.

I may say that the difficulty experienced in anæsthetizing the man was probably due to his being rather a hard drinker.

COMMON DUCT STONE WITHOUT CHARACTERISTIC SYMPTOMS.

By GEORGE EMERSON BREWER, M.D.,
NEW YORK.

The following case is reported as an example of a practically symptomless stone in the common duct; certainly an exceedingly rare condition, and contrasting strongly with those cases of common duct stone, accompanied by septic cholangitis.

C. S., female, aged twenty-two years, was admitted to Roosevelt Hospital during the summer of 1903. For the past four years the patient has complained of occasional attacks of rather indefinite abdominal pain, some of which were accompanied by slight jaundice. Four months ago she had an attack which was, somewhat, more severe than the others, and was accompanied by well-marked jaundice, but without fever. The attack lasted three or four days and then gradually subsided. Since that time she has had more or less discomfort in the upper right quadrant of the abdomen, but no acute pain. The patient has been able to work without interruption, is apparently well nourished, and has shown no sign of jaundice since the last attack.

On examination, the patient presents a clear, healthy skin. The abdominal exmaination was absolutely negative, with the exception of slight tenderness, on deep pressure, over the region of the gall-bladder. Heart, lungs, liver and spleen, normal; examination of the urine, negative. No leucocytosis. The diagnosis of cholelithiasis was made and an exploratory operation advised.

Under ether anæsthesia an incision was made along the outer border of the right rectus muscle. The gall-bladder was found to be normal and free from calculi, as was the cystic duct. Palpation, along the free border of the gastrohepatic omentum, revealed the presence of a hard, movable body in the common duct. This was easily brought to the surface of the wound, by the finger placed within the foramen of Winslow. The duct was cleared and a short, longitudinal incision made, through which a single, round calculus was removed. A probe introduced into the common duct passed easily into the duodenum. The wound in the common duct was closed by the Mayo method, a small strip of gauze tape being left leading to the duct wound. The abdominal wound was partly sutured and dressings applied. The drain was allowed to remain in place twelve days, after which the wound promptly closed. She made an interrupted recovery.

The Buried Animal Suture.—Dr. H. O. Marcy sums up the advantages of buried animal sutures as follows: All aseptic wounds closed with buried aseptic tendon sutures will remain aseptic, and in well-vitalized structures will be followed by primary union. There is no danger of subsequent infection, no expensive and troublesome dressings are required; the subsequent nursing and care are very greatly reduced; no sutures are to be removed, relieving greatly the dread and anxiety of the patient; safety is greatly enhanced and the period of convalescence is shortened. When the work has been done with care the resultant cicatrix is scarcely visible, a matter of much importance in some portions of the body. Operations hitherto impossible have been rendered feasible by the use of buried absorbable sutures—for example, the reconstruction of the pelvic structures, the closing of rents in the peritoneum, etc. The reconstruction of the obliquity of the inguinal canal for the cure of hernia in the male has become an almost everyday occurrence, and should bey et much more widely practised.—*The Maritime Medical News.*

The Use of Hard or Soft Paraffin for Subcutaneous Injections.—Dr. Albert E. Stein concludes, as the result of his experiences, that soft paraffin is less dangerous and more simple of application, and so is preferable for subcutaneous injections. He thinks that the use of paraffin for the prolapses in hernia, etc., is contraindicated, on account of the large amount of paraffin necessary. He sums up his conclusions as follows: (1) The method of paraffin injections is mainly adopted for the correction of small and superficial deformities, such that do not require the injections of large amounts of paraffin. (2) The paraffin to be used should have a melting point of about 41°C. Harder paraffin should only be injected to fill up existing cavities with solid walls. In all other cases it is contraindicated, on account of the greater danger of producing embolism. (3) The mass should never be injected in a fluid from, but is to be used in the form of a paste. (4) There are no sound practical nor theoretical reasons to justify our giving up the use of the soft in favor of the hard paraffin. (5) It is not advisable to inject more than 3 c.c. at one sitting. (6) The injected mass is not absorbed but encapsulated, grown through with connective tissue, so that the result in all cases is a lasting one. (7) The œdematous swelling immediately following the injection, generally disappears in a few days.—*Deutsche medicinische Wochenschrift.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THOMAS L. STEDMAN, A.M., M.D., ASSOCIATE EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, January 23, 1904.

THE CONSOLIDATION OF THE STATE SOCIETIES.

THE plan of consolidation of the Medical Society of the State of New York and the New York State Medical Association presented by the sub-committee of the Joint Committee on Conference has been published sufficiently in advance of the Albany meeting to give ample opportunity for the profession of the State to deliberate on the provisions of agreement and to be prepared to ratify the same intelligently. The appeal to the medical profession of the State by the American Medical Association through the chairman of its Committee on Organization is also equally timely as a companion document, inasmuch as it gives the necessary reasons for the union in question. It was peculiarly appropriate that the National Association should take the initiative in the matter of reconciling the differences in the State organizations, and nothing more appears to be required than a cordial acceptance of conditions offered.

The appeal for unification embodies certain principles which must impress the good judgment of all who wish for harmony of action and the broad equity of common justice to all parties concerned. The hitherto vexed question of ethics has solved itself in a natural and reasonable way. The national body has evolved the solution of the problem by the steady growth of its own consciousness of justice and right, and in the true interests of the profession at large. The motive of conciliation is thus placed on the high level of sound reasoning and impartial interpretation of mutual interests. In 1882, when the Medical Society of the State of New York took its high and liberal stand against professional sectarianism, and declared against mere ethical differences of opinion among legally licensed practitioners of other schools, the innovation was resented by every similar organization throughout the country. At that time the MEDICAL RECORD emphatically declared itself in favor of the measure and virtually stood alone in its advocacy of the new idea. As is well known, the profession of the State was so radically divided regarding the wisdom of such a course that many hundreds of good men and true withdrew their allegiance from the parent society and formed an independent organization since so well known as the New York State Medical Association. Thus New York gloried in two societies differing radically with each other on the question of proper interpretation of the National Code of Ethics. The older society was quite consistently denied representation in the national body, but stood firmly to its convictions. Time only was required to prove that it was in the right. In the light of recent events there can be no question as to the integrity of such a position. The only fault of the society was that it was twenty years ahead of its time and the profession was not willing to endorse what then appeared to be an ill-considered and premature movement.

Fortunately, however, the difference of opinion did not materially affect the strictly scientific work of these separate organizations, as each prospered in its way. In the course of time, however, the original cause of dispute was so far forgotten that the two county societies enjoyed to a certain extent a common membership, making it strikingly evident that there was merely a technical division where there should be a rational union. To a certain extent also the two State societies became reciprocally interested in composite membership. Thus while the roots were appropriately buried, the upper branches easily intertwined. It was a natural method of growth with a proximity of interests. Each party has proved its point as to right of opinion; but now that the original issue is permanently buried by the decision of the higher court, the hitherto divided sections of the profession virtually stand upon a common plane. It logically follows when the cause for secession has been removed, the seceding body ceases as such to exist, and the original State society reinstates itself. In admitting this condition of affairs there is no damaging compromise for either party in the suit. Unification is then only a matter of detail. With common privileges there is to be merely one society instead of two.

There does not seem to be any doubt as to the way this can be effected. At the Albany meeting the proposed amendment to the charter of the old State society should be duly endorsed and the recommendations of the sub-committee unanimously approved. Therefore "let us have peace," one purpose, one motto, and one heart.

VIOLET AND ULTRAVIOLET RADIATIONS.

KNOWING as we always have, that without the radiant energy of the sun, life on this planet would be impossible, it was but a step for the scientist to utilize the various elements of which this energy is composed just so far as he was able to isolate them and guide them to the accomplishment of special purposes.

The present amazing activity in this direction unquestionably dates from the discovery of Röntgen, revealing to us as it did, forces that were hitherto unknown and even unexpected. Other forces as radiant heat and light were known to us in a vague way, but as regards light but little attention was given to it until the persistent Finsen forced us to take cognizance of its wonderful power as a therapeutic agent in the treatment of certain cutaneous affections. Finally radium comes to us suddenly from the unknown, and exhibits phenomena that in some respects appear to shake the very foundations on which much of the physical science of to-day is built.

Of the Röntgen ray we now, after eight years, know that it is an agent capable of much good and also of great harm, but the thousands and thousands of exposures that have been made, have taught us that we may utilize its virtues and protect our-

selves and our patients in great measure from its vices. Of the therapeutic value of radium as compared with other remedial agencies we, as yet, know nothing. Our present knowledge is limited to the bare fact that exposure to the emanations of radium of a given potency and for a sufficient length of time will result in the destruction of tissue. If malignant tissue lie in the path of its radiation, it is destroyed, but so also is normal tissue, and it is to be feared that while much good may be done, much evil will also develop from the indiscriminate use of this powerful form of radiant energy. In time, however, when the various radium preparations are carefully standardized and their effects studied by competent investigators, we may hope to be able to use them so as to do the most good and the least harm.

Of the effects of light and of the obscure radiations that accompany it, we fortunately have a better knowledge, but even this is insufficient to enable us to answer many of the questions that daily confront us. We know that a portion of the visible spectrum composed of the shorter wave lengths (blue-violet) can penetrate the body to a certain depth, and the photographic experiments of Franklin and of Kime teach us that some of the radiations can completely traverse tissues of even notable thickness; we know further that these radiations readily traverse glass and the other bodies that we commonly term transparent. Finsen more forcibly than any one else, has taught us that these luminous radiations can be controlled and their energy directed to the accomplishment of a beneficent purpose.

In addition there are other rays, so-called, that are of shorter wave length than those of violet light, but which are invisible to us and are made known only by the effects they produce on other bodies. These ultraviolet rays are, in a measure, utilized by Finsen. Of them, however, we know that they will readily traverse disks of quartz cut from the natural crystal, ice, rock-salt, and Iceland spar, but utterly refuse to traverse the clearest glass; and their direct action on the skin is extremely superficial. Despite this fact, unexplainable as it now is, there is no question as to their powerful action on some forms of morbid tissue.

One of the most interesting features connected with the violet and ultraviolet radiations is the effect they produce on certain minerals, in developing the phenomena of fluorescence and phosphorescence. For instance, if the violet rays be isolated and caused to impinge on the mineral willemite a greenish glow is immediately perceived, and if a piece of glass be interposed the fluorescence persists. If, however, the ultraviolet rays be isolated and caused to impinge on the same mineral the fluorescence is much more brilliant, but ceases immediately if the mineral be protected by a piece of glass as thin as a spectacle lens. Willemite from Franklin Furnace N. J. now scarce and difficult to obtain is sometimes associated with calcite. If such a piece of mixed mineral be exposed as before to the violet rays, the willemite will fluoresce, but the calcite is apparently unchanged. On exposure, however, to the ultraviolet the calcite immediately changes to a bright pinkish-red.

These tests appear to us to be of considerable practical importance, as it will enable the operators in great measure to differentiate the rays and in time to determine which are the more useful and efficient in the treatment of disease, concerning which we have but very vague and uncertain information at present.

THE ANNUAL REPORT OF THE BUREAU OF ANIMAL INDUSTRY.

This report contains several papers of more than general interest. Dr. D. E. Salmon, presenting the report of the committee on animal diseases and animal food to the American Public Health Association, takes strong ground against Koch's view of the distinctness (and therefore the reciprocal incommunicability) of bovine and human tuberculosis. The author reviews at considerable length the more recent work in the direction of infecting animals by inoculation with infected human tissues or cultures. He considers that these investigations are now sufficiently numerous and sufficiently harmonious in their results to establish the following conclusions: (1) the bacillus tuberculosis found in human tuberculosis differs greatly in its pathogenic powers as obtained from different cases; (2) two types of tubercle bacilli may be obtained from man, namely, one which is somewhat difficult to cultivate, which grows slowly, and the bacilli of which are short, stubby, and free from beading—the so-called bovine type, and a second, which is quite easily cultivated, grows rapidly, is longer, thinner, and inclined to show beaded and curved forms—the so-called human type; (3) virulent cultures may be obtained from both of these types, which, when inoculated according to the methods used by Koch and upon the species of animals specified by him, produce progressive and fatal tuberculosis; (4) the contention that human tuberculosis cannot be transmitted to asses, sheep, goats, swine, and especially to cattle, has been completely disproved; and (5) Koch's failure to produce tuberculosis in the animals named, with bacilli from human sources, was probably due to the use of bacilli of low pathogenic power.

Salmon then cites several cases of recent record as to the transmission of bovine tuberculosis from cattle to man, and says: "Considering these facts in connection with those of similar bearing previously reported, it may be said that the transmission of bovine tuberculosis to man is fairly well established. The apparent inoculation of a human subject with bovine tubercular material, the development of a tubercular process at the point of inoculation, the isolation from the human tissues months afterward of a tubercle bacillus having the characteristics of the bovine bacillus constitute a chain of evidence that is conclusive." And he reaches the following conclusions: Recent investigations show that while the bacilli of human tuberculosis are often of feeble virulence for cattle, there is a considerable proportion of cases in which these bacilli are virulent for cattle as well as for other animals. Bacilli of both the bovine type and the human type have been obtained from cases of human tuberculosis. Bovine bacilli introduced into the human tissues by accidental inoculations have lived, multiplied, and produced disease at the point of inoculation, and have been recovered after a considerable time with

their vitality and virulence unimpaired. Various statistical studies indicate that a considerable proportion of the cases of human tuberculosis, and particularly with children, originate through the ingestion of the bacilli with contaminated food.

Prof. F. C. Harrison gives the results of his studies upon the viability of the tubercle bacillus in cheese. From his original experiments carried out in Switzerland, we are, he considers, safe in concluding that hard cheese—especially Emmenthaler—is quite safe for human food as far as tuberculosis is concerned. Both Cheddar and Emmenthaler are seldom eaten until they are four months old or more; at this age all tubercle bacilli which they may have contained will be dead. We should also remember that the number of tubercle bacilli likely to be present in cheese as commonly made is very small, and that in all probability those will die sooner than bacilli put into cheese in the course of experiments like these. Besides this, the original number of such germs in milk will be reduced by being carried off in the whey. From the experimental data it would seem advisable to use the milk of tuberculous cows, segregated according to Bang's system, for making cheese rather than butter—that is, on the assumption that the latter is made without proper Pasteurization of the milk or cream. The whey from such milk should be heated to 85° C. (185° F.), which would not only kill any tubercle bacilli that might be present, but would also have other excellent economic results. Since his return to America, Harrison has extended his observation to American cheeses. These later experiments fully verified the conclusions first reached, and justify, in the author's opinion, this statement: If Cheddar cheese, as commonly made in the United States and Canada, happens to contain tubercle bacilli, naturally present, it may be assumed that none of these germs will be living when the cheese becomes ten weeks old; hence no danger need be apprehended of acquiring the disease known as consumption by eating well-cured Cheddar cheese.

Reporting from the committee above mentioned, Dr. Salmon emphasizes strongly the too prevalent apathy toward rabies in this country. The one method of controlling the disease, the muzzling of dogs, will not be tolerated by the sentimentally minded, and it appears that the medical profession has contributed somewhat to the popular errors concerning this disease by uncertainty of doctrine and by failing to take as decided a stand as it should upon a question of so great importance. In 1901 in Minnesota the State Board of Minneosta had knowledge of eighty-five cases (ten dogs, seventy cattle, four hogs, one horse), and of seventy-three cases for the first ten months of 1902. The Bureau of Animal Industry made a positive diagnosis of rabies in twenty-five cases in and around Washington during the year ending June 30, 1902, one of them being in a woman, yet there are no measures enforced for the suppression of the disease. Salmon also sounds a warning as to other animal diseases communicable to man, especially glanders, of which three cases were reported to the Minnesota Board of Health in 1902, and anthrax, which appears to be increasing in frequency and territory.

The long period that this infection may remain active in certain soils makes an outbreak of it in any locality a very serious matter, since it is never known when or how often the disease may reappear. Great care should be taken in handling carcasses of animals dead of either glanders or anthrax. All contaminated soil should be scraped up and buried with the carcasses, the whole being well covered with quicklime. Autopsies on such diseases should be made with the greatest care, one of the three Minnesota cases having originated in this way.

Malaria and Its Prevention.

Major Ronald Ross read a paper on "Malaria in India and in the British Colonies," at a recent meeting of the Royal Colonial Institute.

In the first portion of the paper the author referred to the extent to which malarial fever prevails in the tropics, a prevalence far more widespread and with a much greater mortality and sick-rate, than is commonly supposed. For instance, in India, the British troops in 1900 numbered 60,653; among these there were, during that year, admitted to hospital for malaria 19,445 men, fifty deaths occurred, while the constantly sick were 710. These figures were taken from the report of the Sanitary Commissioner with the Government of India. The same report states further that out of 305,927 persons comprising the European and native armies and the goal population, no less than 102,640, or about one-third, were admitted into hospital for malarial fever during the year 1900, and among the entire population of India no fewer than 4,919,591 deaths were attributed to fever within twelve months.

Major Ross said that "as a whole, however, India is by no means an intensely malarious country. The attacks from the disease among French troops in Algeria vary from 65 per cent. to 221 per cent. of the strength per annum, the death rate reaching 2 per cent. of the strength. Among the British troops in Sierra Leone from 1892 to 1898 the admission rate averaged 213 per cent., and the death rate 4.2 per cent. per annum."

With regard to prevention the author points out that there are many difficulties in the way of successfully so doing, not the least of which is the incredulity manifested by the community at large as to the mosquito being chiefly instrumental in spreading malaria. In Africa itself, notwithstanding the fact, that four years have passed since the discovery was made that mosquitos are the carriers of malaria, the bulk of Europeans in Africa reject it, so that if the prevention of the disease depends upon the conversion of the public, many years must elapse ere definite results are obtained. From these considerations, argues Major Ross, it follows that for immediate results at least we must look chiefly to State action which does not depend upon the conversion of the public, but only on that of the rulers; it can be adopted immediately; and moreover will benefit the largest number of people for the least amount of money and expense. State measures for the repression of malaria have already been tried in Sierra Leone, Havana, Legros, Ismalia, the German Colonies, Hongkong, and many other places. In Ismalia the results have been conspicuously successful, and the crusade against the mosquito in Havana has reflected great honor on those who conducted the sanitary regeneration of that city of evil reputation.

Major Ross concluded by saying that "we may rest assured that if we wish for a continuous policy against malaria and the other great diseases of the tropics, the sanitary system must be reorganized. . . . On the whole, perhaps, malaria can be dealt with more easily and effectually than any other great disease—than tuberculosis, cholera or plague, for instance; and at the same time it constitutes a

most serious bar to the development of many countries."

It is always a difficult matter to bring the general public to a realization of the true facts of the case relating to the origin and propagation of disease. Even an educated layman is inclined to believe in old-time views, rather than in what he often regards as the fantastic theories advanced by modern men of science. As for the general masses, they do not take enough interest in affairs outside their own sphere, to concern themselves with the manner in which a malady like malarial fever is spread. Therefore, Major Ross is probably in the right when he contends that at present the repression of malaria should be conducted by the State.

Degeneracy of the British Children.

The question of defective children is one that is being widely discussed in Great Britain at the present time. The poor of great cities, and especially of London, are, owing to a variety of causes, greatly handicapped in the battle of life. The children are born, in many instances, mentally and physically deficient, and their environment, lack of proper food, and pressure of education tend to accentuate these failings. Dr. George Still has recently written on the subject and presents the theory that wrong-doing in children is not ordinary "naughtiness," but moral imbecility. In fact, many children are born degenerates and are not responsible for their actions. Associations, too, exercise a great influence on the child's nature, and when the taint is present, the subject grows up and develops into a criminal. Education, it is declared, is of no avail to render such children respectable members of society. On the contrary, it only has the effect of making them worse.

The London School Board has recognized that these "moral deficients" must be dealt with in an exceptional manner, and are organizing homes in which they can be segregated and carefully watched. It has also been proposed to appoint a royal commission to decide what measures shall be taken with mentally and morally defective children. According to the *London Daily Mail*, "in the minds of some of the promoters of this step is the idea that means should be devised to separate such children, when of an age to be out of the control of any scholastic authority, from the rest of the world. Such a course is held to be necessary if the growing evil is to be checked."

Great Britain does not have a monopoly of degenerate children. In New York and other large cities of the United States moral imbeciles are by no means unknown. It might be well if the example of the London School Board were followed and efforts made to grapple with the evil.

Therapeutic Value of Yeast.

The *Journal of the British Royal Army Medical Corps*, December, has an editorial dealing with yeast as a therapeutic agent. Beer yeast, the product referred to, has long been known as a home remedy for boils, carbuncles, and other inflammatory conditions. According to the editorial in question, Preston and Taruella (*Revista de Med. y Cirurgia*, June 15, 1901) were the earliest workers to adduce experimental proof of the value of yeast, the most important of their conclusions being the following: (1) Beer yeast exercises a local and general curative action upon streptococcal and staphylococcal infection in rabbits, when administered hypodermically for five to twelve days in 10 c.c. doses of a well-grown culture; (2) similar injections repeated for four consecutive days render rabbits immune to these coccal infections; (3) the curative principles of yeast are intracellular and act only after liberation by a leucocytic or humoral ingestion of the cell; (4) blood serum of rabbits treated by yeasts has an agglutinating action upon streptococcus and staphylococcus albus and aureus. Yeast cultures in beef and barley medium show this same power after two days' growth and lose it when heated to 55° C.: (5) mixed cultures of yeast and streptococcus and staphylococcus produce attenuation of the virulence of the latter; (6) in the pus of a subject treated by yeast the pyogenic organisms decrease in number and in virulence.

It is further stated that only about seven-tenths of an average sample of beer yeast consists of saccharomyces cerevisiæ, the rest being impurities. If a yeast be kept in a dry but cool place it is capable of secreting its soluble ferments after a long lapse of time; moisture and warmth alter its character rapidly, mainly by enabling the impurities to replace the true saccharomyces cerevisiæ. The results obtained by yeast in the treatment of boils and carbuncles are apparently due to its antiseptic, phagocytic, and immunizing action, not to any specific action upon particular pathological lesions. Infantile diarrhœa infective and micromembranous enteritis or dysentery, have all been much relieved by the action of beer yeast.

In 1895 Cassaët recommended beer yeast for the treatment of diabetes mellitus, its beneficial action in this disease depending upon the conversion of all starchy elements into alcohol. Boigey confirms these statements.

Many other diseases are said to be much benefited by treating with yeast. The claim is not made for yeast that it is by any means a universal panacea, but it is asserted that, judging from experimental and clinical facts, it is a valuable remedy.

The Bacillus Coli Communis as an Indication of Sewage Contamination of Water Supplies.

Major W. H. Horrocks, British Royal Army Medical Corps, writes at length on this subject in the journal of the corps for November. The author points out that although the bacillus coli communis has been regarded as one of the most important indications of sewage contamination of water, nevertheless much confusion exists as to the cultural characteristics which are to be considered diagnostic of this particular organism. He then shows that the cultural reactions may vary to a wide extent when the organisms are grown on ordinary nutrient media.

The experiments conducted by the author are illustrated by a somewhat elaborate table, to which he constantly refers when explaining the results of his investigations, so that within the limits of an editorial it would be almost impossible to follow his reasoning. His conclusions, however, are as follows: (1) The bacillus coli communis is the only organism of the coli type on which implicit reliance can be placed as an indication of sewage contamination. (2) The bacillus coli communis should not be present in 200 c.c. of water derived from properly protected deep wells and springs. (3) If bacillus coli communis be not found in 10 c.c. of upland surface waters it is practically certain that the supply has not been contaminated with human fecal material. At the meeting of the American Public Health Association, held in Washington in October last, Mr. H. W. Clark and Stephen D. Gage of Boston read a paper "On the Value of Tests for Bacteria of Specific Types as an Index of Pollution," which was reported in the Medical Record

November 14. In the course of their paper the authors pointed out that tests for bacillus coli at the Experimental Station at Lawrence had agreed well with results obtained by chemical analysis and by inspection of the sources of the samples. Surface waters having the greatest relative population on their watershed had shown bacteria of the colon type more frequently than others with less population. Ground waters, on the other hand, unless grossly polluted, never showed bacteria of the colon type. Samples of shellfish from sources polluted and unpolluted had almost invariably shown the presence of bacillus coli in the polluted samples, and their entire absence in the non-polluted samples.

Judging from the conclusions arrived at both by the British writer and by the American writers, the presence of the bacillus coli communis is a sure indication of sewage contamination of water supplies.

News of the Week.

Medical Society of the State of New York.—The annual meeting of this society will be held at Albany Tuesday, Wednesday, and Thursday, January 26, 27, and 28, 1904, under the presidency of Dr. Algernon T. Bristow of Brooklyn. The first morning will be devoted to executive business, chiefly a discussion of the plan for the union of the two medical bodies in the State. On Tuesday afternoon there will be a symposium on "Diabetes," and on the evening of the same day President Hadley of Yale University will address the society on the "Conflicting Claims of General Education and Professional Education," and the president of the society will deliver his annual address. On Wednesday afternoon there will be a symposium on "Abdominal Pain," and on the same evening very appropriately will be eaten the annual dinner preceded by the reception of the President at the Hotel Ten Eyck. On Thursday morning there will be a symposium on "Nephritis," which it is hoped will be of sufficient interest to prevent the usual stampede of the last day of the meeting.

Jubilee of the New York Infirmary for Women and Children.—The fiftieth anniversary of the founding of this institution was celebrated at the Waldorf-Astoria on Saturday evening, January 16. An address was made by Dr. William H. Welch of Johns Hopkins University. He congratulated the infirmary on its great work in the past and wished it success and prosperity. The infirmary anticipated the need of trained nurses, he said, and marked in a small measure an epoch in the development of hospitals and the care of the sick poor in this country. Women had demonstrated that they had the same fitness as men for the study of medicine, he said, and there was no reason why the same opportunities should not be afforded to them as to men. An address by Dr. Emily Blackwell, read by Dr. Robbins, said that with the growth of the institution and the increasing cost of modern requirements for hospital equipment and management, a point had been reached where broader support had become necessary for the successful carrying on of the work. The trustees felt that the fifty years' work of the infirmary had proved its value in the city, and justified them in asking from the public effective assistance in the effort they had initiated to place the institution on a secure foundation. Addresses were also made by Miss M. Carey Thomas, president of Bryn Mawr College, and Dr. Annie S. Daniel. The report of the trustees stated that an effort was being made to raise an endowment fund of $400,000. Up to the present time only about $50,000 of this fund had been subscribed.

Quarantine of a Hospital.—On account of the development of diphtheria in two of the patients, the Orange (N. J.) Memorial Hospital has been placed under quarantine by the Board of Health. The patients have been placed in an isolating pavilion, but no new patients can be received at the hospital until the quarantine is raised.

The Duval County, Florida, Medical Society.—At the recent annual meeting of the Duval County Medical Society, at Jacksonville, Fla., the following officers were elected: *President*, Dr. R. H. McGuinness; *Vice-President*, Dr. Edward N. Liell; *Secretary* and *Treasurer*, Dr. Jay H. Durkee.

The Medical Club of Philadelphia.—At a collation given by the Medical Club of Philadelphia on January 15 a loving cup was presented to Dr. Guy Hinsdale, for five years secretary of the club, and who is about to remove to Hot Springs, Va. The following officers were elected for the ensuing year: *President*, Dr. E. E. Montgomery; *First Vice-President*, Dr. Roland G. Curtin; *Second Vice-President*, Dr. Wharton Sinkler; *Secretary*, Dr. J. Gurney Taylor; *Treasurer*, Dr. F. Savery Pearce, *Governor*, Dr. E. L. Duer; *Executive Committee*, Dr. Hobart A. Hare, Dr. Alexander McAllister, Dr. Walter L. Pyle, Dr. Ernest Laplace, Dr. W. H. Warder.

The Orange Mountain Medical Society held its annual meeting on January 8, at the home of Dr. H. P. Gerbert, Main Street, Orange, N. J. Dr. Gerbert was the retiring president, and he read a paper on "Rheumatism in Children." The officers were elected as follows: *President*, Dr. T. S. P. Fitch; *Vice-President*, Dr. R. Newton; *Treasurer*, Dr. J. Minor Maghee; *Secretary*, Dr. R. D. Freeman; *Reporter*, Dr. H. A. Pulsford; *Executive Committee*, Dr. Chandler and Dr. Bradshaw.

University of Chicago.—Plans for the enlargement of the medical department of this university will involve the addition of three new clinical departments—medicine, surgery, and obstetrics; the erection of new laboratories on Marshfield, opposite the Hull biological laboratories, the provision of a temporary dispensary near the university; the provision at the earliest date possible of five hospitals for medicine, surgery, obstetrics, diseases of children, and contagious diseases, to cost, with endowment, $1,000,000 each; the raising by Rush Medical College of $1,000,000; the completion of the group of buildings, of which the Senn Memorial is the first part, cost $350,000; the organization of a school of dentistry, and a nurses' training school.

The Physician's Fee.—A Philadelphia judge has given expression to the opinion that "the life of a rich man is worth more than the life of a poor man, and the physician has a right to charge the millionaire more for his services than he does the laborer." He went on further to say that "The physician is unlike the merchant, who has goods of different quality to sell at various prices. He must give his best service in every case. But it does not follow that the service is worth the same in every case. Human life has a pecuniary value of variable quantity, greater in the millionaire than in the laborer. Thus, the practitioner of common sense has a maximum and a minimum charge, and makes out his bills to suit the pecuniary circumstances of his patients." From this view there will be no dissent on the part of right-thinking people.

Prevention of Tetanus.—The members of the Academy of Medicine of Cincinnati have taken steps looking toward the suppression of the toy pistol and blank cartridge, which, in this section of the country at least, have been the cause of many sad deaths from tetanus. The Fourth of July celebra-

tion always has its list of victims. In the past year there were five in Cincinnati alone. The patients are of course usually young and vigorous boys, who but for these dangerous toys should have grown to be useful citizens. The Academy has, through the Health Officer, Clark W. Davis placed a resolution before the City Council requesting that an ordinance be passed making the sale or use of toy pistols, blank cartridges, and torpedo canes an offense against the statutes.

Loss of a Bequest.—Mrs. Harriet W. Wykes of Springfield, Ohio, left in her will the sum of $2,500 to Christ's Hospital, Cincinnati. The will provided that a large farm belonging to Mrs. Wykes be sold and the bequest paid from the proceeds. After making this will Mrs. Wykes deeded the farm to Miss Clara Crane of Springfield, so the bequest must go unpaid.

Typhoid Fever in Columbus.—Typhoid fever is still on the increase in Columbus, Ohio. During the forty-eight hours ending January 14, fifty new cases were reported. The Health Department has warned the citizens not to drink the water from the Scioto River without previous boiling.

A Crowded Hospital.—On January 12 the number of patients in the Cincinnati Hospital had reached 630, the largest number ever in the hospital at one time. This condition was brought about by the large number of cases of typhoid fever, measles, and influenza, with an increased number of accidents due to the slippery streets. The number of cases treated in the past year was greater than ever before in the history of the hospital.

Graduation of Nurses.—The Cincinnati Hospital Training School held its annual graduation exercises on January 14. Eighteen nurses were graduated.

Philadelphia Polyclinic and College for Graduates in Medicine.—Corporator's Day was observed on January 11, in addition to the presentation of reports by the trustees, the faculty, the Training School Committee, the hospital, the college department and the election of trustees, the enlarged children's ward, the new nurses' home, the new power and electric-light plant and the new laundry building were formally opened, and the hospital and laboratories were inspected.

Hospital for the Treatment of Infectious Diseases.—A new hospital will be constructed soon on the south side of the city of Chicago. Plans are now being considered for the erection of buildings where the work of the Memorial Institute for Infectious Diseases will be carried on, and its scope greatly increased. Special provision in the shape of a laboratory will be made at the new hospital for a continuation of investigation of scarlet fever and other diseases.

Radium in the Waters at Bath.—It is stated that Professor Dewar has found helium in the gases arising from one of the mineral springs at Bath, England. Some weeks ago a quantity of the iron deposit collected in the tanks and pipes of the New Royal Spring was obtained and sent to the Hon. R. Strutt, son of Lord Rayleigh, who made a careful investigation of the material, and reported he had found that the deposit contained radium in appreciable quantities, though not enough to make extraction profitable. He thought there could be little doubt that the helium of Bath owed its origin to large quantities of radium at a great depth below the earth's surface. A little of this radium was carried up by the rush of hot water and was found in the deposit.

High Death Rate in Philadelphia.—For the week ended January 16 there were reported to the Philadelphia Bureau of Health 736 deaths, the largest number in any week for three years. More than 25 per cent. of the entire number were due to acute affections of the air-passages, including the lungs. There were from pneumonia 93 deaths and from bronchopneumonia 37 deaths, and 12 deaths were attributed to congestion of the lungs.

American Laryngological, Rhinological, and Otological Society.—The annual meeting of the Eastern Section of this society will be held at Fall River, Mass., on Saturday, January 30, under the chairmanship of Dr. George L. Richards of Fall River. The secretary of the society is Dr. Wendell C. Phillips, 40 West Forty-seventh street, New York City.

Examination for Medical Clerk.—The United States Civil Service Commission announces an examination on February 17 and 18, 1904, at the usual places, to secure eligibles from which to make certification to fill eighteen vacancies in the position of copyist (male), at $900 per annum, in the Bureau of Pensions, and other similar vacancies as they may occur. The examination will be in letter-writing, penmanship, copying, anatomy and physiology, diagnosis, general and special pathology, and surgery and surgical pathology. The age limit for candidates is twenty-five to thirty years. Only graduates of recognized medical schools may be examined. Persons who desire to compete should apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312, which should be properly executed and filed with the Commission at Washington.

St. John's Guild has published its thirty-seventh annual report for the year 1903. It maintains two floating hospitals and a seaside hospital. It carried 35,549 women and babies on its boats last summer and treated 955 cases of illness among the latter.

Neglect in the Registry of Births.—Registrar Evans of Cincinnati complains that physicians and nurses will not send to the Board of Health any report of births in the city, and consequently the statistics are faulty and misleading. Several physicians, he says, when asked for reports have refused to make them, saying they could not be compelled to do work for nothing.

Census of Physicians in Germany.—The annual "Medical Calendar" of Dr. Schwalbe, just published, states that there are 29,997 medical practitioners in Germany, an increase of 864 during the year. Berlin has 2,572 physicians, or one to 734 inhabitants; Charlottenburg, one to 373; Dresden, one to 952, and Elberfeld only one to 1,843. Twelve women obtained from the Government, in 1903, the right to practise medicine. The number of dentists has increased much more rapidly proportionately than that of physicians. In 1876 there were but 498 dentists in Germany, with a population of 35,000,000, but in 1903 there were 1,922 dentists in a population of 58,000,000.

Bequests to Philadelphia Hospitals.—By the will of the late Henry B. Ashmead of Philadelphia, his estate, valued at $500,000, is to revert to the Episcopal Hospital, as a memorial to his wife, after the death of his widow and his daughter. By the will of the late Louis C. Vanusem the sum of $25,000 is devised to Jefferson Medical College Hospital.

The Michael Reese Hospital of Chicago is to be rebuilt at a cost of more than $250,000. A special committee recently met to provide funds for demolishing the old structure and erecting a new one. The committee decided that to build a suitable

edifice at least $250,000 would be required. Already $115,000 have been subscribed.

Superintendent of the Presbyterian Hospital of Chicago.—Dr. Arthur B. Ancker, for twenty-one years superintendent of the city and county hospital in St. Paul, Minn., has been appointed superintendent of the Presbyterian Hospital of Chicago. He will take charge February 1.

Bellevue Hospital Appointments.—At a meeting of the Trustees of Bellevue and allied hospitals, held January 8, 1904, Drs. Frederick Peterson, Joseph Fraenkel, Edward D. Fisher, and Bernard Sachs were appointed alienists and neurologists to Bellevue Hospital.

Consulting Sanitarians to the Health Board.—Health Commissioner Darlington of New York has appointed Dr. Ernst J. Lederle, whom he superseded as commissioner, and Prof. Charles F. Chandler, who served as one of the commissioners of health several years ago, as members of the advisory board in the capacity of sanitary officers.

Suit for Rontgen-ray Burns.—A resident of Chicago has sued a physician of that city for $25,000 damages, alleging that the doctor burned his face with the *x*-rays. He says that before treatment he had a heavy mustache and beard, and that now the beard will grow on only one side of his face.

Smallpox in New York State.—The weekly bulletin of the State Board of Health reports that new cases of smallpox have appeared during the past week in Salamanca and West Salamanca, Plattsburg, Middleport, Cambria, and Massena. The epidemic which had prevailed extensively in the village of Medina appears to have subsided. The young women students at Wells College, Aurora, are under quarantine because of a case of varioloid among them. All the students have been vaccinated, and it is hoped there will be no more cases in the college.

The Ills of Royalty.—The Emperor of Russia is reported to be suffering from pleurisy supervening upon an attack of influenza. The cable reported a few days ago that King Edward was suffering from a serious throat malady, but this has been contradicted, and it is said the report originated in the fact that he had a very slight catarrhal sore throat while visiting in Derbyshire, and consulted the local physician because of it. King Christian of Denmark, who has been sick at Gmunden, Austria, for some time, has so far recovered that he was able to return to Copenhagen on Sunday. The German Emperor is reported to have recovered entirely and read his speech at the opening of the Reichstag last week in a clear ringing voice. The Empress Augusta Victoria of Germany is suffering from a slight injury of the foot, which has necessitated the postponement of certain court functions.

The Late Dr. Cyrus Edson.—At a meeting held January 12, 1904, the Medical Board of the Willard Parker and Riverside Hospitals adopted a resolution to the effect that "In the death of Dr. Cyrus Edson the profession has lost a broad-minded physician and a progressive and scientific sanitarian, who labored with tireless energy, intelligent effort, and marked executive ability in the office of Commissioner of Health and the subordinate offices in the Health Department which he held before he attained the commissionership." And also that "The Medical Board holds in affectionate remembrance the uniform courtesy and kindness of which each of the visiting staff of these hospitals was the recipient during Dr. Edson's administration of the Health Department. Ever ready to discuss projects for the welfare of the hospitals, he gave them full consideration and approval, if possible, and the aid of his executive power in their accomplishment."

Obituary Notes.—Dr. FREDERIC W. VANDERSLOOT died at York, Pa., on January 13 at the age of seventy years. He was graduated from the University of Maryland in the class of 1856.

Dr. HENRY L. TOLMAN died at his home in Evanston, Ill., on January 14, at the age of fifty-five years. He was a member of the faculty of the College of Physicians and Surgeons of Chicago.

Dr. WM. H. IRELAND died at Camden, N. J., on January 12 at the age of sixty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867.

Dr. EDWARD Dolan of Worthington, Minn., died suddenly on January 2 at the age of thirty-five years. He was born in Waterville, Minn., in 1868 and was graduated from the Bellevue Hospital Medical School in 1892. He practised in Worthington, except for a period of study in Europe, until 1898. At the outbreak of the war in that year he organized Company H, Fifteenth Minnesota Volunteers, and was commissioned Captain. At the close of the war he spent some months in post-graduate study in this city and then resumed his practice in Worthington.

Dr. PULASKI F. HYATT died at Jersey Shore, Pa., on January 17 at the age of sixty-nine years. During the Civil War he was a surgeon to Carver Hospital, Washington, D. C. In 1876 he was sent to Florida as the personal representative of Samuel J. Tilden, to superintend the counting of the vote in that State. In 1891 he was appointed a trustee of the Danville Hospital, and in 1893, United States Consul to Santiago de Cuba.

Dr. EDMUND S. HANNA, for many years a practising physician of Pittsburg, died of apoplexy January 18, at his residence, East Orange, N. J. He was born in Steubenville, Ohio, seventy-five years ago, and was graduated from Jefferson Medical College, Philadelphia, in 1850. He began practice in Pittsburg and was surgeon of the Allegheny County Workhouse, the Children's Church Home, the Baltimore and Ohio Railroad, and the Allegheny Valley Railroad for many years. He retired in 1888 and moved to Boston, but took up his residence in East Orange eight years ago.

The Fatality of Whooping-cough.—Eliza H. Root calls attention to the fact that this disease is too little dreaded by the medical profession, and that it is by no means the simple affair that many seem to suppose. From the United States census of 1900 we find that 663 died in New York from whooping-cough, and 549 from scarlet fever. In Chicago 141 died from whooping-cough, and 373 from scarlet fever. Philadelphia, 179 from whooping-cough, 182 from scarlet fever, and so on in the different cities. Death from whooping-cough occurs most frequently from pneumonia as a complication, that induces heart failure, or a bronchitis may occur that ends in suffocation. Asphyxia or marasmus, due to the continued ejecting of the food or loss of appetite may cause death. Cerebral apoplexy, external hemorrhage, and emphysema of the subcutaneous tissues after rupture of the larynx is occasionally given as the cause of death. Even when death does not occur, severe disturbances of the nervous system may remain, as weakness of the intellect and memory, imbecility, hemiplegia, with consequent chorea, epilepsy, etc. Visual defects, strabismus, blindness and deafness, partial or complete, and even deaf-mutism may remain. Whooping-cough, it is evident, should be under the control of health authorities, subject to quarantine and other preventive measures as much as scarlet fever.—*Woman's Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PROPOSED HOSPITAL BOARD—SLEEPING SICKNESS—HOSPITAL SATURDAY FUND—BART'S AND KING'S HOSPITALS—STATISTICS OF HOSPITAL PATIENTS—OBITUARY NOTES.

LONDON, January 1, 1904.

IN the general lull of the holiday time and the interest excited by appeals to charity it is interesting to note that the questions involved in the subject of hospital management have found expression in the *Times*. One correspondent, whose communication is assigned great prominence, suggests the formation of a small competent central board by the King's, the Sunday, and the Saturday funds. Some such central advisory board is no new proposal, but as this one is supported by a leader in the *Times* it is gaining a good deal of attention. The three funds have given a great impetus to the collection of money, and have also exercised a good influence on managers who have so long felt no restraint on extravagance. They are also promoting amalgamation of competing institutions, though success in this direction is less than might have been anticipated. It is doubtful whether such movements will eventually lessen the evils they are designed to meet. Competition may have redeeming qualities, and those who dislike the distribution arrangements are disposed to ask why, if amalgamation be a panacea, do not these three funds begin at home with the process and present themselves as the united central advisory body. Such a board would exercise enormous influence as long as it confined its efforts within its proper sphere of advising, because, its advice, when followed, would be supported by pecuniary contributions.

Two natives from the Congo Free State were landed at Birkenhead on Monday suffering from sleeping sickness. They were taken to the Liverpool Tropical School. Three patients left the Congo, but one of them—the wife of one of the two survivors—died of the disease when nine days out from Matadi. The two arrivals are probably between twenty and thirty years old and only appeared rather drowsy, so that an inexperienced observer might not have noticed their condition.

The incident gives point to a paper on the disease read at the last meeting of the Epidemiological Society by Dr. Sambon, whose name is indissolubly connected with the subject. You will remember that as soon as Castellani discovered a trypanosoma in sleeping sickness many at once guessed that a fly might be the carrier. Guesses were very well, but Sambon and Brumpt set to work to settle the question and both announced simultaneously a successful search. Their researches were undertaken to support Castellani's discovery by a study of the distribution and life-history of tetse-flies on the one side and the epidemiology and distribution of sleeping sickness on the other.

At the last annual meeting of the British Medical Association, Dr. Sambon stood alone as a supporter of the causal relationship of Castellani's trypanosome and sleeping sickness. He said then he saw no difference between that and Trypanosome gambiense, and pointed out that its so-called posterior extremity was in reality the anterior. Further, he pointed out that it played the part also of an alternative host. After reviewing some other contributions, Dr. Sambon gave details of experiments undertaken to determine whether the glossina palpalis carried the infection of sleeping sickness. Flies fed on patients and then, after eight, twenty-four, and forty-eight hours, on monkeys, were employed. About two months later the trypanosomes were found in the blood of these monkeys. Similar results were obtained at Entebbe. As to these, certain objections had been made, and Dr. Sambon considered them inconclusive. This seems obvious, as the flies were not fed on patients but caught and used at once. It is a striking fact that monkeys bitten by flies not fed on patients contracted the disease in the course of two or three weeks, while those bitten by flies which had previously been fed on patients did not contract it for eight weeks. That showed that the flies did not get the parasite from the blood of the patients, who, as a rule, seldom had them in the peripheral circulation, but that, while biting, they emptied themselves of some of the parasites they were carrying.

Sir P. Manson made a long speech, in the course of which he related how he had at one time been convinced that the source of infection was the filaria perstans, but the hypothesis had been destroyed at a stroke when it was found that the disease prevailed extensively in districts in which this filaria was hardly to be found. Now he believes that the trypanosome is the cause, but is constrained to admit that the proof is not absolute. Until that is the case he thought there was reason for refraining from advising extensive public measures on what possibly may turn out to be an erroneous hypothesis. He urged the injection of pure cultures of trypanosomes into monkeys (or if any experimenter was self-sacrificing, to try it on himself) as the first test.

Prof. Ray Lankester felt interested from a natural-history point of view, but doubted whether it was correct to call these parasites in mammalian blood trypanosomes, though he knew that a competent naturalist took an opposite view. He quite supported Sir P. Manson's attitude, and remarked that they were learning so much about minute parasites in mammalian blood in the tropics that the greatest care was required in forming conclusions. The possible coexistence of another parasite should not be overlooked.

Dr. M. E. Brumpt of Paris referred to the doubts that had been expressed and stated his belief that his researches in Africa, followed by those in Paris, in conjunction with Dr. Wurtz, established an absolute coincidence between the presence of the parasite and the disease.

The year has been a good one for the Hospital Saturday Fund. It is cheering to hear, among the many statements of failing resources, that this fund has received nearly £15,000 more than in any previous year, and the greater part of its income is derived from the penny-a-week collection. It is expected that £6,000 or £7,000 may yet be sent in by the local committees and the accounts will not be closed until January 11, in order to include every sum for the year 1903.

The post office has secured the refusal of a part of the site which was thought to be at the disposal of Bartholomew's Hospital. If the post office take it over that will settle the scheme for local enlargement advocated by many. Probably the post office would be willing to forego its right in favor of the hospital, if public opinion be expressed with sufficient explicitness.

The Lord Mayor's appeal for the Middlesex Hospital is being widely circulated, the good work done in reference to cancer giving point to the plea for help.

With the close of the year statistics of all kinds are being discussed. Here is an example: The number of patients in the fever and smallpox hospitals last week was 2,601; in 1902 at the corresponding date, 3,628; in 1901, 5,071; in 1900, 4,185. The population of London according to the census of 1901 was 4,536,541.

Dr. Charles F. Moore of Dublin died on the 25th ult., aged eighty-three, after a very brief illness. Only three days previously he was at work. In early days he practised a little while in London, but soon returned to his native country where, in the course of his long career, he filled many offices—Medical Officer of Health, Physician to the Fever Hospital, Inspector of Seamen, Certifying Surgeon under the factory acts. This last he retained up to his death, and was engaged in connection with it on the Monday before his death. He had been president of the Dublin Academy of Medicine.

The death is announced, on the 23d ult., of Dr. R. J. Blair-Cunninghame, J.P., ex-president of the Royal College of Surgeons of Edinburgh. Born in 1841, he took M.D. Edin., 1862, with gold medal in Forensic Medicine, became F.R.C.S., Ed., 1866, and M.R.C.P., Ed., 1877. He was also F.R.S., Ed., Superintendent of Statistics in the Registrar-General's Department, Scotland, and had held many other offices in the course of his career. He was president of his college in 1892.

Anæmia Infantum Pseudoleukæmica of von Jaksch.—marks that it seems to be a disease with too much leucocytosis to be classed with pernicious anæmia; too little leucocytosis, a spleen too enlarged in proportion to the size of the liver, and too little lymphatic infiltration, for leukæmia; and with none of the enormous conglomerate enlargement of the lymph nodes seen in pseudoleukæmia. It is possible that the disease is really a transition stage of one of these three. The spleen is very large and hard and shows a hyperphasia of all its tissues, with an increased quantity of leucocytes in its structure. The liver is less enlarged, of uniform consistence and shape, and shows no lymphatic infiltration. The lymph nodes are moderately enlarged and do not fuse together. As to blood changes, the erythrocytes are reduced to 400,000, and show many of the degenerative changes of severe anæmia. The leucocytes run from 20,000 to 100,000 with the relative proportions of the several varieties, not always the same in different cases.—*St. Louis Courier of Medicine.*

OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

THE HAMADIEH HOSPITAL—THE MILITARY MEDICAL SCHOOL AND HOSPITAL—THE STATUS OF MEDICINE IN TURKEY—CHLOROFORM SYNCOPE—NECROLOGY—HEALTH OF THE CITY.

CONSTANTINOPLE, November 15, 1903.

THE building of the Hamadieh Hospital at Constantinople —to which allusion has been made in former letters—may be considered as marking a period of medical progress in Turkey. This establishment, though generally known as the Children's Hospital—was intended for the treatment of women and children. It was founded by his present Majesty Sultan Abd-ul-Hamid—the second—February 2, 1898, and is named "Hamadieh," after its founder. It was constructed after the model of the hospital "Reinicken-Darf," near Berlin, under the superintendence of Dr. Ibrahim Pacha, who was sent to Germany with the special object of studying and selecting a model hospital for children. The inauguration took place June 5, 1899, with the usual religious ceremonies, conjointly with those of the circumcision of an Imperial Prince.

The site of the hospital is at Chichli, a suburb of Constantinople, and no more beautiful nor healthy site can be imagined for the purposes of an hospital. It was the wish of His Majesty that it should be constructed and arranged on the most modern principles, and be fully equipped with the most recent appliances. It is really a series of well-built stone pavilions, scattered over a large extent of garden, where grow shady trees under which the patients may lounge and play.

GENERAL VIEW OF THE HAMADIEH HOSPITAL.

Attached to the hospital is a policlinic with its special departments of pharmacy, laboratories, and reserved chambers, with comfortably furnished consulting and waiting rooms. The policlinic is also furnished with ophthalmic dark chambers and all necessary appliances and instruments for this branch of medical science. Special consulting rooms for internal diseases, gynecology, and diseases of the nervous system, ears, and throat; arrangements for electrotherapeutic purposes, and a large saloon is set apart for surgery, in which are displayed an array of surgical instruments, sterilizing and other apparatus of the most recent kind.

The staff of the hospital and policlinic consists of the most distinguished native doctors. Dr. Ibrahim Pacha, director and physician in chief Two distinguished operative surgeons, Drs. Kambouroglon and Djemil Pacha; chemists bacteriologists, radiographers, pharmacian in chief, with four assistant pharmacians, specialists in diseases of eyes, ears, throat, etc., dressers, dentist, and bandagist.

The nursing staff is superintended by the Sister Superior of the German Deaconesses Nursing Establishment of Zehlendorf near Berlin, with four other German nurses, and male and female trained native assistants. To the policlinic alone are attached a score of doctors who, for five days in the week, alternate their services. Women and children of all nationalities are attended, and the value and utility of these services in a country like Turkey will be appreciated from the fact that since the opening of the hospital, May, 1899, to the end of February, 1902, the total number of women and children treated was 45,178—Moslems, Greeks, Armenians, Jews, and foreigners. Since the foundation of the hospital other useful pavilions have been erected.

The medical officers attached to hospital and policlinic are graduates of the Imperial School of Medicine, who have mostly been sent to France and Germany to complete special studies. Thus the staff, titular and honorary, are competent to meet the requirements of progressive medicine and surgery. His Majesty, the Sultan, takes a special and personal interest in the development of this hospital, and no expense is spared to maintain it as perfect as possible.

Another medical institution of Turkey is worthy of notice, *i.e.* the new Military Medical School and Hospital at Haidar-Pacha, on the heights of the Asiatic shores of the Bosphorus. On the anniversary of His Majesty's accession to the throne—this month—the establishment was formally inaugurated with much pomp and religious ceremonies. There is not a more imposing edifice of its kind in Europe. It has accommodation for 1200 students, and when completed and fully organized will provide instruction in every branch of medicine and surgery. Museums of physics, natural history, large botanical gardens, chemical and bacteriological laboratories, and an autirabic institute are parts included in the program of the future. The Military Medical School of Gul-Hané will be transferred to this building, which has been several years in course of construction.

These two institutions, full of promise, are, and it is hoped will continue to be, monuments of a reign which has been characterized by educational advancement. For whatever may be thought of other branches of national education in Turkey, the progress of medicine and its allied sciences have had a very remarkable development during the last fifteen years.

In many respects it may be imitative—indeed, is so—yet a very sound and solid spirit of emulation has been aroused, and we find Turkish teachers of medicine stimulating their students by referring to the teachings and practice of their Moslem—Turkish and Arab—forefathers, who cultivated medicine as a science centuries before

Europe did, and regretting that instead of profiting by the teachings of their own learned ancestors, they should have to borrow from Europe the elements of a science that had been highly developed in the East centuries ago, and further illustrating the subject by references to the contagion of phthisis and plague, the etiology and treatment of syphilis and itch, quoting from the writings and teachings of Avicennes, the Haralies-Mehmed bin Ehou-Bekir-il-Razis—Seid Mehemmed—Iben Bechir, and other learned Moslem medical writers of the past. In short, that medicine had reached its apogee in the Ottoman Empire three or four centuries ago!—a somewhat conservative Moslem view of progressive medicine, but none the less praiseworthy.

The Medical Society has resumed its winter meetings. Djemil Pacha related a case of great interest. Operating on a man thirty years of age, for anal fistula, who had inhaled 10 grams of chloroform, heart syncope occurred. After two minutes' trial of ordinary means to restore animation without success, he opened the thorax and practised massage of the heart, which had ceased to beat. The heart movements were reëstablished, and some respirations secured. Unhappily the patient succumbed.

It is gratifying to record that the CO_2 process of Mr. P. Apery of Constantinople for destroying rats on shipboard has been recommended by the International Congress of Paris.

The death of Dr. Khorassandjiau, a practitioner of repute, house physician to the Hamadieh Hospital, and professor of pathology, is a distinct loss to the profession.

The health bulletins of Constantinople and suburbs have shown for some months past a notable decrease in the number and mortality of infectious diseases, especially typhoid fever.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

THE KAISER'S HEALTH—THE SOCIAL DEMOCRATIC PARTY AGAINST THE MEDICAL PROFESSION—RADIUM RAYS AND THEIR EFFECT ON MICROBES—FINSEN'S TREATMENT OF ERYSIPELAS—PANCREATIC JUICE AND DIABETES—THEORY OF DIABETES

BERLIN, December 15, 1903.

THE Kaiser's health is almost restored. His Majesty lately received the members of the Imperial Reichstag, and hardly any hoarseness could be noticed. Preparations are made for his sojourn on the Mediterranean on board the imperial yacht *Hohenzollern*.

At one of the recent debates at the Reichstag reference was made to the position of the medical profession in regard to the clubs, "Kassenvereine." The Imperial Chancellor Count von Bûlow was denouncing the Social Democratic party, which obtained a vote of three millions at the last election, and he referred to the terrorism which the leaders of the medical clubs, mostly members of the Social Democratic party, applied to the physicians of the clubs. It will be remembered that the position of the profession to these clubs is gradually decreasing through the enormous increase of medical men in Germany. Consultations at the rate of forty pfennig (ten cents) are frequently given. Only very recently the medical profession has organized itself against the clubs. An organization, whose head is the Leipsic Union, has been formed, and several places where a dispute between the doctors and the clubs had originated have been boycotted, and *mirabile dictu* the medical profession succeeded in its efforts. As in Germany, every workman is a member of such clubs, it is obvious that the clubs form a great clientèle, and young physicians generally commence with them. Efforts are made to adopt a system which enables the workman not to be compelled to consult the very physician who belongs to his club, but to give him a chance to consult any physician belonging to a certain association. A centralization of the clubs with one head office is also aimed at. This would be advantageous to the doctors as well as to the clubs, for there are several clubs, such as the tailors' and dressmakers' clubs, whose members are almost always ill, and constantly have to consult the doctor; whereas others, the members of the butchers' clubs, for instance, enjoy a robust health.

At a recent meeting of the Berlin Medical Society, Dr. Miethe reported on the physical qualities of radium. When the *x*-rays were discovered some years ago similar rays were sought for in the light of the moon. But no likeness could be found between *x*-rays and rays of the moon. Though there are many kind of rays which have a photochemical influence none are analogous to the *x*-rays. It was Becquerel who found in the element uranium some characteristic rays resembling the *x*-rays. He found that photographic plates were affected, when pitchblende was near, the effect being due to the radium contained in pitchblende. Whether radium is one element, or whether it is a combination of several elements, has not yet been ascertained. Radium is found, together with other minerals, in very small quantities. Giese was the first who succeeded in separating this radioactive part through fractional crystallization. The principal quality of radium is the capacity of sending out rays by itself and also of making other bodies fluorescent. The radium rays penetrate all bodies, neither metal nor boric offering an obstacle whereby they differ from the *x*-rays. Dr. Caspari continued the subject and reported on the bactericidal action of radium. Together with Dr. Aschkinass he has experimented at the Institute of Infectious Diseases. He found that radium rays prevent the growth of microbes and that they kill pathogenic microbes. Similar experiments have been made by Pfeiffer and Friedberger. Caspari injected radium into the body of animals suffering from various diseases, but no definite results were obtained.

The effect on carcinoma is known. Several patients have been treated with radium rays at the Moabit Hospital and at the Charité, but no definite statement as to the results of such treatment can be made at present.

Finsen's red-light treatment of erysipelas was the subject of discussion at the Medical Section of the Silesian Society by Dr. Paul Krause. He treated twenty patients suffering from erysipelas with red light. Of his patients eighteen suffered from erysipelas of the face, and they were treated in 11.5 days (on an average). Krause thinks, however, that the therapeutic effect is no better than with ichthyol.

Neisser demonstrated some photographs of patients suffering from variola vera treated with Finsen light. Red light was employed, and in all cases complete restoration resulted, no signs of a scar remaining. According to Neisser, the red-light treatment can have no effect on erysipelas, as the red rays have no influence on microbes, but only on inflamed tissue.

Blumenthal read a paper before the Society for Internal Medicine on the glycolytic ferment and on diabetes. His interesting report may be summarized as follows: According to the latest scientific researches there exists but one organ capable of causing diabetes, namely, the pancreas. The liver only regulates the glycolysis. The piqûre of Claude Bernard and extirpation of the suprarenal glands do not cause diabetes but glycosuria. Only through the extirpation of the pancreas is a real diabetes caused. Lepine thought that the pancreatic juice contained an element capable of destroying sugar, and that diabetes was caused through disease of the pancreas then incapable of destroying the sugar of the human body. But this view could not be proved through experiments made by Kraus and Minkowski. Glycolysis is due not only to the pancreas, but every organ may form it. Cohnheim of the Physiological Institute of Heidelberg has found that there is glycolytic ferment in the muscles, a ferment which gives a real diabetes when pieces of the pancreas are added. From these facts Cohnheim concludes that diabetes is not caused by one ferment only, but that two are always necessary. Miss Hirsch found in the liver 23 per cent. of sugar, but pancreatic juice added to it gave 63 per cent. In the blood Nadine Lieber has found that fibrine is a strong glycolytic ferment, whereas blood serum contains a strong antiglycolytic ferment, so that glycolysis is rendered impossible in the blood. For if a glycolytic process took place in the blood it would soon be saturated with carbonic acid, whereas a glycolytic process in the muscles causes an increase of the body temperature and kinetic energy results. Therefore the leucocytes only imbibe the ferment and transport it to the pancreas, where the juice forms active glycosuria, *i.e.* diabetes. Blumenthal's conclusions are that all organs have a glycolytic ferment, which transforms sugar into carbonic acid and water, not alcohol, that the pancreatic juice in combination with a special ferment, causes active glycosuria, and that in diabetes the ferment of the pancreatic gland is missing.

The gold medal for scientific researches has been awarded to Professor Ehrlich of the Serotherapeutic Institute of Frankfort-on-Main by the Imperial Government.

Local Anæsthesia for Inflamed Tissues.—A valuable local anæsthetic for inflamed tissues can be had by adding a few drops of 1-1000 solution of adrenalin to a ½ to 1 per cent. solution of cocaine. In injecting this, the first result is an anæmia of the skin, due to its action on the vasoconstrictors, followed by a deep anæsthesia. Incisions can be made into inflamed tissues with the loss of very little blood, and the method is well adapted for furuncles, anthrax, etc.

SUBMUCOUS RESECTION OF THE NASAL SEPTUM.

To the Editor of the Medical Record:

Sir: An article with this title, by Dr. Felix Cohn, has appeared in a recent issue of the Medical Record. Dr. Cohn's references in it are exclusively German, and I should like to call his attention to American work on the subject in the form of two articles by me. "The Correction of Deflections of the Nasal Septum with a Minimum of Traumatism," *Journal of the American Medical Association*, March 8, 1902, and "The Window Resection Operation for the Correction of Deflections of the Nasal Septum," *Journal of the American Medical Association*, Vol. XLI, 1903. In these papers I advocate the continuing of the resection as far back into the bony septum as necessary and describe an original set of instruments made by me for the work, and a technique developed by my experience with sixty operations.

Contrary to Dr. Cohn's views, my results have shown me that the resection method is an ideal one for all varieties of deflections of the septum. I have had but one perforation in ten cases, due to my early awkwardness in performing the operation. Of late I feel practically certain of not perforating. There have been no complications following the operations, and in all but two of my first cases the nostril has become entirely freed from obstruction.

I am greatly pleased to find an advocate for the resection operation in Dr. Cohn, and think that he may advise its employment with less reserve than he has shown in his article. By giving me credit for my work on the subject you will greatly oblige me. Otto T. Freer, M.D.

288 Huron Street, Chicago.

THE PSYCHICAL RELATIONS OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir: In your issue of the 2d of January there appeared an article by Dr. S. A. Knopf, entitled "A Plea for Justice to the Consumptive," in which this author devotes a great deal of space to the discussion of a recent article of mine on "The Psychical Relations of Tuberculosis in Fact and Fiction" (*New York Medical Journal*, August 1 and 8, 1903). In view of the attitude which Dr. Knopf assumes against me, and in view of the fact that he has not only invoked the authority of such men as Osler, Tyson, Janeway, Bowditch, Biggs, etc., in his attack upon me, but has actually proposed for adoption certain resolutions relative to this matter before the Society of Medical Jurisprudence, I am forced to appeal to you for an opportunity of justifying myself in the eyes of your readers by stating my side of the case.

Those who know Dr. Knopf personally or through his extensive writings, know how enthusiastic he is on the subject of phthisiophobia, and how persistently he has waged a battle against this mode of thinking. In his quest for examples of phthisiophobia among physicians he has come across my article, and straightways has seized upon it as on valuable clinical evidence of this very rare disease among the medical men of this country. It is with regret, therefore, that I am obliged to correct Dr. Knopf's diagnosis in my case, and to submit incontrovertible proof of the fact that I am free from phthisiophobia. It is a pity; for in the cause of science one is always glad to find an example of an extremely rare disease.

The only explanation which occurs to me for Dr. Knopf's diagnostic error in my case is that he has not cared to read my article in its entirety, for the same reason that he "has had no time or inclination to refute all my conclusions." Had he taken this trouble, he would certainly not have presented me before the Society of Medical Jurisprudence, as his "star case" of phthisiophobia among physicians.

The article to which Dr. Knopf refers does not pretend to advance new or original views on the subject of the mental characteristics of the tuberculous patient. It is merely a synthetic review of this theme, based chiefly upon the works of such authorities as Heintzelmann, Letulle, Cornet, Dettweiler, Bernheim, Chartier, Skulteki, Cioffi, Mircoli, Mafucci, and others. Analyzing the mental state of the tuberculous, it touches briefly upon the relations of tuberculosis, insanity, and crime—questions which are by no means solved as yet, and which I present simply in their unfinished condition, as a guide to further researches by those who are competent to pursue them.

From this article Dr. Knopf took two sentences and used them for the construction of two questions which he sent out to such eminent authorities as Osler, Tyson, Janeway, etc. In speaking of one of the cases reported in a previous paper, by Dr. Fanoni, in which a man spat everywhere deliberately, so as to prevent his young wife from surviving him, I say: "*Here* psychasthenia, the loss of self-control, and the rise of brute selfishness have combined to distort the clearness of ethical perception," meaning, of course, by "here, *in this case*. I cite also a number of other cases of crimes committed by consumptives under circumstances which warrant a suspicion that there may be a connection between the disease and the crime. Nowhere do I say that a greater tendency to crime has been noted among consumptives than among other individuals, nor that the *average* consumptive, as the result of the mental peculiarities of which I have spoken, exhibits a distorted ethical perception. Yet this is exactly what Dr. Knopf represents me as saying in his letter of inquiry sent to Professors Osler, Tyson, Janeway, Biggs, etc. I am not at all astonished that not a single one of these gentlemen endorsed such statements, and should have been greatly astounded if they had done so.

To those of your readers who have not the time or the inclination to go back to my article for proof, let me quote a few sentences which will satisfy any unbiased man that I have been placed in an untenable position by distorting my own statements and by omitting all explanation:

"I do not pretend that my analysis is complete or that every consumptive is bound to exhibit the specific traits that I have discussed, *much less* that every consumptive is a mental degenerate or a candidate for the jail or the lunatic asylum." "(6) In all probability there is a connection between tuberculosis and insanity, the tuberculous toxin contributing, *with other factors, in persons rendered susceptible by psychical and somatic degeneration, to the derangements of the mind.*" Does this signify that the *average* consumptive is inclined or predisposed to insanity? "(7) The criminal tendencies of consumptives have been observed *with sufficient frequency* to justify an investigation into the medicolegal question of restricting the responsibility of a criminal on the ground that he is tuberculous." Does this tally with the impression which Dr. Knopf gives your readers, that I consider the *average* consumptive inclined to immorality and crime as the result of a distortion of ethical perception? Does a man who advocates, as I do, leniency for a criminal under the law, on the ground that he is consumptive, discriminate *against* the consumptive, as Dr. Knopf would have me do, or does he, on the contrary, discriminate *in favor of* the unfortunate victim of tuberculosis?

As regards the mental traits of the average consumptive, I show upon the authority of every observer who has written on the subject, that tuberculosis is to a certain extent responsible for the mental make-up of the patient, especially in the advanced stages of the disease. The only theory which has sufficient experimental and clinical basis, as regards the mental changes in the consumptive, is that of toxic poisoning of the central nervous system by the products of the tubercle bacillus. Neurasthenia and psychasthenia are prominent factors in a great many consumptives, and as the result of this, there comes into play the keynote of most of the later mental changes in tuberculosis, namely, the gradual loss of will power, of self-control, and the ascendance of selfishness. These traits have been commented upon by a number of writers on the psychology of tuberculosis. Nowhere do I deny that the noblest characters, the greatest minds, are found among consumptives. To do so would be to manifest glaring ignorance and violent phthisiophobia. On the contrary, the wide range of variations in mind and temperament among consumptives, according to the previous character of the sufferer and the gravity of his condition, is fully brought out in my article. The abnormally increased susceptibility to external mental influences, the extreme variability of temper, and the increased tendency to rapid nervous and psychical fatigue in consumptives, are too well established to need any comment or defence.

One of the speakers in the discussion of Dr. Knopf's paper characterized as ridiculous the resolutions proposed against my conclusions, as Dr. Knopf conceived them. No man who is in his right senses could say that all consumptives are insane or are inclined to be criminal, and, aside from the fact that not a jot or tittle of the laws of the universe can be changed by passing resolutions against them, a resolution against an absurdity, dangerously borders upon the antithesis which is often so close to the sublime.

But one more word as regards the term "phthisiophobia." Such words have no business in medical terminology. They introduce a spirit of bias into the consideration of questions of fact. The texture of medicine should be made up of experimental, statistical, biological, and physiological data, and into its woof and warp should not be brought the threads of passion and prejudice. To brand a man with a name implying that he is an evil-wisher of the race, or of a large part of it, is not consistent with the calm, subjective, unbiased methods of modern medical research. Nothing can be proved

pro or *contra* in this matter of tuberculosis and crime by calling any one a phthisiophobe, any more than by adopting resolutions to the effect that two and two do not make five, all opinions to the contrary notwithstanding. No physician can be a phthisiophobe if he has put an elementary knowledge of the etiology of tuberculosis as brought out by modern study. No physician can be a phthisiophobe who possesses the instinct of his calling—the ideal of his destiny—the consciousness of his power for mankind's welfare.

G. A. DeSantos Saxe, M.D.

294 West Ninety-second Street, New York City.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Jan. 14, 1904.

Mercuric Cyanide as a Surgical Disinfectant.—Charles Harrington has made careful experiments to determine the germicidal property of mercuric cyanide. He used silk threads impregnated with various cultures and subjected them to a 1-1000 solution of the pure salt. He believes that his results can lead to but one conclusion concerning the practical value of mercuric cyanide. A substance which, when employed in the strength recommended, cannot destroy all known species of pus organisms within three hours, and in double that strength accomplishes nothing in thirty minutes, can hardly be classed among the efficient germicides.

Intermittent Hydronephrosis.—M. H. Richardson reports this case of intermittent hydronephrosis. The patient was a man twenty-three years of age. For six months he had had pain in the left side about two inches below the ribs. He had been completely disabled for this time. There was a large tender mass in the region of the left kidney. It was impossible to see if fluctuation was present. Examination of the urine was negative. Examination of the blood showed nothing abnormal but a leucocytosis. Within five days the mass had entirely disappeared. The history for the next few months was about the same as before. An incision over the site of the tumor was made. The peritoneal cavity was opened sufficiently for a thorough exploration of the right kidney and other abdominal organs. Examination of the left kidney showed its pelvis much enlarged and thickened. But it contained no stones. The case was clearly one of hydronephrosis, caused by a sharp bend in the ureter at its origin at the pelvis of the kidney. A careful dissection was made of the renal pelvis and of the ureter to show the relation of the parts and the cause of the obstruction. An incision about an inch in length was then made extending through the pelvis of the kidney and down half an inch on to the ureter. The middle of the incision corresponded to the sharp angle of continuity between the pelvis and the ureter. This longitudinal slit was converted into a transverse one by appropriate sutures, a small wick was placed at the line of suture on the left. In a month the patient was entirely well and able to work.

The Bicycle as a Therapeutic Agent.—Luther Halsey Gulick calls attention to that class of cases in which the patient is constantly demanding treatment for either real or imagined functional disorders. In discussing the indications for treatment, the writer says that in bicycling alone do we find both the physiologic and psychic conditions adequately met. This exercise has various factors in its favor. It is taken out of doors. Rarely are rooms so well ventilated as to be as fresh as country air. The direct effect of sunlight upon the tissues is secured out of doors and not indoors. One of the immediate results of bicycle riding is a large increase in the respiration. The effects of these increased respiratory movements upon the viscera constitute one of the important beneficial results of the exercise. The alternate pressure and relaxation which the diaphragm exerts upon the liver is a large factor in promoting the various circulations within that organ. Success or failure depends upon the accurate adaptation of the exercise to the individual need. The writer always tests the capacity of the individual for the exercise. He counts the heart beat after a certain time given to the exercise and then calculates the proper amount of exercise and its distribution in point of time. The bicycle saddle must be properly adjusted and the patient's spine must not be bent in the dorsal or lumbar regions. The spine may be erect or inclined forward. The writer believes the bicycle to be a useful therapeutic agent in cases in which it is desirable to quicken the general organic functions of circulation, of respiration, and of digestion. It offers besides ample diversion and out-of-door air. It provides for exercise of the large muscular masses by a great number of small efforts. It is automatic and so productive of comparatively little fatigue.

Journal of the American Medical Association, Jan. 16, 1904.

A Parasitic Maggot in the Skin of an Infant.—F. L. Washburn reports a case of this nature, the laws being that of *Gastrophilus epulepsalis*. The patient was a female infant three weeks of age, born prematurely at the seventh month and bottle-fed from birth. One of these maggots came from a pustule on the back of the neck, one from the palm of the hand, one from beneath the jaw, and one from between the great and second toes of the right foot. The infant had slept in its carriage out of doors for many hours nearly every day since its birth.

The Immediate Relief of Hysterical Manifestations of the Larynx.—H. W. Loeb says we must gain the confidence of the patient and then apply suggestion. He informs his patient that the first word the latter will utter after treatment is finished is the word "home." He inserts the right index-finger into the pharynx and presses the epiglottis over the glottis until the patient becomes somewhat uncomfortable, when he withdraws the finger and says in a loud commanding voice, "Now, say home, home, home!" The patient responds, and the command is continued as often as necessary until the patient repeats not only "home," but any word suggested, and leaves the office cured (!) He reports various cases of hysterical aphonia from different causes treated in this way.

Sources of Plague.—W. J. Calvert gives an historical sketch of the early plague epidemics and describes the bacillus isolated in 1894 by Kitasato and Yersin. The disease originated in Egypt, formed new endemic homes, and has spread along the routes of commerce. The bacillus is tenacious of life, and is spread by merchandise, rats, and convalescents. It thrives best in unhygienic places and affects mostly the lower classes of society. As to direct transmission, it is to be borne in mind that as septicæmia develops in the course of the malady all the excretions become infected. Of special importance are the urine, fæces, and sputa. In pneumonic cases the sputa are laden with bacilli, and in delirium may become a dangerous source of infection, as the bacilli may be spread broadcast over the room and those in attendance.

Medical News, January 16, 1904.

The Surgical Treatment of Acquired Incontinence of Urine in Women.—Charles Greene Cumston discusses in this paper only the condition of acquired incontinence of urine. He first considers incontinence having a traumatic urethral origin. Injury of the internal aspect of the urethra is a condition which is particularly met with in various cases of dilatation of the canal. The dilatation may be pathological, produced by the passage of a calculus or a neoplasm. Surgical dilatation of the urethra is far less often resorted to now than formerly, on account of incontinence of urine which often follows it. Incontinence sometimes follows later, the traumatism acting on the vaginal wall of the urethra. Forceps or manual operations during labor may injure the urethra. Some patients progressively develop an incontinence of urine when no former history of traumatism of a surgical or obstetrical nature can be elicited. In certain cases of uterine displacements, especially in prolapsus uteri, incontinence develops. Vaginal cicatrices are at times associated with incontinence. The surgical treatment of this affection will vary according to whether the urethral canal is present or not. In cases of abnormal traction on the urethra, due to prolapsus uteri, appropriate treatment must first be directed to the uterus before considering the bladder symptoms. In cases of abnormal adhesions between the bladder and the uterus, the adhesions must be freed. This can be accomplished by making a transverse incision over the anterior aspect of the cervix and then peeling the bladder off the organ. The wound is packed with gauze and allowed to granulate. If incontinence follows operation for vesicovaginal fistula, examination should be made for cystitis. If this is negative, there may be present bands of cicatricial tissue which drag upon the urethra. These bands should be divided, and, if necessary, the bladder be separated from the uterus. If more or less destruction of the sphincters exists, electricity, combined with massage, will sometimes restore the tone. Operation may, however, be necessary. When incontinence seems due to a more or less complete destruction of the urethral canal, the urethra must be repaired, and the organs replaced in their normal relations. Much patience must be exercised by both surgeon and patient in all of these procedures.

The Hemorrhagic Diseases and Their Allies in the Light of Modern Pathology.—F. L. Wachenheim, after discussing the nature and causation of spontaneous hemorrhage, takes up the autogenic hemorrhagic diseases. He states that the failure to acquire immunity is the

corollary to his theory of hæmophilia, as the disease itself is a pathological immunization. There is in obstructive icterus an autointoxication that presents a blood condition practically identical with hæmophilia except as to permanence. The presence of agglutinins has been demonstrated in the blood in jaundice, evidenced by its action in cultures of the typhoid bacillus. Such formation of agglutinins requires the presence of a toxin. If biliary obstruction and resorption continue for any length of time, an extensive production of anti-auto-agglutinins is inevitable. The resemblance of idiopathic hæmophilia to icterogenic hæmophilia is striking and convincing. Of the precise nature of the scurvy producing poison, little as yet can be said. Scurvy presents a considerable resemblance to rachitis—a non-hemorrhagic disorder. The writer divides the exogenic hemorrhagic diseases into three classes, on the basis of etiology: Chemical blood poisoning; non-infectious toxinæmia; infectious toxinæmia. The antipyretics of the anilin group offer a characteristic series of blood poisons. The most typical and powerful of the blood toxins is snake venom. Various similar animal secretions, as the venom in the bites and stings of insects, differ from it chiefly in degree, and that only apparently, considering quantitative relations. That all of the infectious diseases may be attended with hemorrhagic symptoms is not surprising when it is considered that they are all more or less toxinæmias. The writer sums up his paper as follows: Hæmophilia, congenital or acquired, is a toxinæmia with secondary autoimmunization to a quasi-normal function; that the scorbutic affections are chemical autointoxications, hemorrhagic only because the blood is especially involved; and that the purpura rheumatica group is only a manifestation of ordinary rheumatism or sepsis. After this exposition of their very diverse nature, it seems clear that the old class of the hemorrhagic diseases has become obsolete, should be relegated to the domain of historic medicine, and cease to appear in our monographs and textbooks to further puzzle the student and physician.

New York Medical Journal, January 16, 1904.

The Relation of Early Diagnosis and Treatment to the Prevention of Tuberculosis.—F. M. Pottenger says that it is not necessary, in order to make a diagnosis of tuberculosis, to wait until bacilli appear in the sputa. A skilful physician should be able to detect the disease from the clinical history and the findings of a physical examination. If these are insufficient, the tuberculin test should be applied. The character of the disease changes completely as it advances. At first it is a pure tuberculosis, but later becomes a mixed infection. Sanatorium care offers the best conditions for a cure. Latest statistics show that over 30 per cent. of all cases thus treated are permanently cured.

Psychic Healing or, Properly Speaking, the Treatment of Disease or Supposed Disease by Mental Influence.—E. W. Lee mentions several of the methods by which charlatanism flourishes, showing that many of the wonderful "cures" performed by non-medical persons are, in cases of real success, merely methods of applying suggestion; but he makes the point that those who do not understand disease have no right to treat it. Often an individual, suffering from a very serious condition, is lulled into a fool's paradise by the plausible incantations of some charlatan, and, for the time being, made to forget his true condition. But herein lies the danger. Such cases often, by rational treatment, could be benefited, but under the influence of quack suggestion, the disease goes on until it is too late to be amenable to scientific treatment.

American Medicine, January 16, 1904.

Malaria Followed by Interstitial Nephritis and Peripheral Neuritis.—Otto Lerch reports this case. The patient was a man of fifty-six years. He had an attack of estivoautumnal malaria. Both albumin and casts were found in the urine. Blood examination showed 30,000 white cells. Plasmodix and a large number of crescents were found. Muscular weakness of the left arm and hand was especially marked, and the sensation of touch and pain of the third, fourth, and fifth fingers of the left hand and the outer part of the thigh was lost. A pin could be thrust deep into the skin without the patient noticing it. The adjoining parts, however, were rather hypersensitive to touch as well as to pain. The sense of heat and cold was not disturbed. Numbness and other abnormal sensations were constant in these areas. The area affected in the hand corresponded to the cutaneous distribution of the ulnar nerve, and that of the thigh to the external cutaneous, though adjoining nerve fibers were involved.

Hallucinations of Vision.—Howard F. Hansell speaks first of errors of refraction. He states that myopes have an inaccurate impression of size, distance, color and detail, and erring their judgments of matters concerning which their information at least chiefly, comes through their organs of vision. The patient with paralyzed ocular muscles receives two impressions of every object, neither of them correct. The mental impression of opacities of the cornea is that of cloudiness; of opacities of the lens, that of a fog; of opacities of the vitreous, that of smoke. Irritation of the rods and cones of the retina and the axes cylinders in the nerve and retina by the pressure of blood or inflammatory material accentuates the normal activity of the tissues, and the field of vision is occupied by brilliant meteoric displays of flashes and circles of light. True hallucinations of vision are independent of ocular conditions, and are properly preferable to mental disorders.

Appendicitis.—J. J. Brownson believes that there are three periods in which the operation for appendicitis can be safely performed: (1) At the inception of the disease before fever. (2) After the fever and distention have subsided and suppuration has taken place. (3) In the interval after all signs of inflammation have disappeared. He says that there have been more deaths from appendicitis since the operative method has been in vogue than during the expectant plan. He believes that this is due to interference being practised at the wrong time. He concludes that the operation for appendicitis ought to be done in the primary or before-fever period. The appendix should be removed, to guard against fulminating cases and those in which rupture occurs into the abdominal cavity. In the secondary period, after suppuration, drainage should be instituted, and nature left to take care of the appendix. In the interval, after all symptoms of inflammation have subsided, the appendix should be removed. The operation ought not to be done in the intermediary period when there is fever and distention of the abdomen, because the danger from operation at this time is greater than the risk of the case becoming fulminating, or the abscess bursting into the abdominal cavity.

The Lancet, January 2, 1904.

Ascites Rapidly Cured by Iodide of Potassium.—The patient of J. A. W. Pereira was a man of twenty-five years, whose abdomen was distended with fluid. The urine contained a little albumin, but there was no jaundice, liver enlargement, œdema of eyelids, face, or extremities. The fluid disappeared under purgatives and diuretics, but soon returned, this time involving the legs and genitals. Tapping was thought of, but the man was under the usual age of alcoholic cirrhosis, and did not have the hepatic facies of the tippler. The author concluded that there was some pressure on the portal vein, and that probably a gummy deposit. Accordingly the patient was given iodide in small doses, which acted as a powerful diuretic, and he was soon relieved of the fluid.

Ochronosis.—By this term, W. Osler refers to the pigmentation of cartilages, sclerotics, and the skin in alkaptonuria. He reports two cases, brothers, aged respectively fifty-seven and forty-nine years in whom the pigmentation was distinctly recognized in the ear cartilages, sclerotics, and in one, by a remarkably ebony-black discoloration of the skin of the nose and cheeks. Alkapton is the name given to a yellowish resinous body occasionally found on urine which, on exposure assumes a brownish color. Osler believes that his cases support Albrecht's view that the pigmentation of the cartilaginous tissues is associated with the remarkable disturbance of metabolism heretofore recognized only by the changes in the urine. As far as is known, no symptoms in the few recorded cases have been directly referable to the alkaptonuria. The article contains a brief report of previously reported cases.

An Effectual Means of Dealing with the Conditions of Chronic Obstruction of the Large Bowel Resulting from the Adhesions Which Develop in Consequence of Chronic Constipation.—Basing his plan on the fact that experience had shown that the ileum had been connected with the sigmoid flexure or with the upper part of the rectum to deal with various troubles arising in special and rare cases, such as cancer, obstinate atony of the colon, intussusception, fistulæ, and the like, and that the result had been excellent so far as the nutrition of the patient was concerned, W. Arbuthnot has determined to employ this method as a routine treatment in the definite group of cases of obstruction of the intestine produced by adhesions and by an acquired momentum in which the complete division of these constricting media will not afford relief, the recurrence or continuance of symptoms being produced by their reformation. He makes a very free lateral anastomosis between the lower limit of the ileum and the upper part of the rectum, or the sigmoid flexure if the rectum is too bound by fixation of the sigmoid flexure to allow of its being readily handled. For this purpose an

efficient anastomosis can only be made by sacrificing a portion of the circumferences of both ileum and large bowel sufficient to insure that the resulting lumen at the junction shall not exceed the original size of the large bowel. The result of such operative treatment has been very satisfactory, the patient being freed from pain and tenderness, losing the dirty color and inactivity consequent on the absorption of ptomains, improving in weight, and obtaining regular daily evacuations by means of mild purgatives. The only objection to the lateral anastomosis is that the presence of any very large quantity of solid fecal matter in the vicinity of the opening in the large bowel may possibly cause fæces to pass on into the cæcum. For this reason it now divides the ileum, closing its distal aperture and making its proximal section open into the lower end of the large bowel, so rendering it impossible for any material to enter the cæcum.

Deceptive Signs of Improvement Following upon Septic Intoxication in Acute Appendicitis, Especially in Young People.—W. H. Bennett calls attention to the fact that the subsidence of pain, tenderness, swelling, and rigidity in the right iliac fossa is no evidence that an appendicitis case in a young person is passing out of the danger zone. This fact holds even though, with the foregoing apparent improvement, the pulse may fall and the temperature improve. Under these conditions of apparent safety, a gangrenous condition may be present in the appendix. Two illustrative cases are narrated presenting the abovenamed course of symptoms. In the first, operation disclosed gangrene; in the second, operation was deferred. Bennett finds that decision as to operation in such cases depends on two points: (1) The condition of the temperature, and (2) the aspect and mental mood of the patient. On the latter he lays special stress. A flushed and dusky cheek, black lines under the eyes, furred tongue, dulness, inertness, etc., all suggest danger, while a cleaning tongue, brightening mental state, etc., are signs of improvement. The dulness is due to septic intoxication, and an improvmeent in the local physical signs must not mislead us. Decrease of pain in a septic patient does not necessarily mean improvement, unless it is accompanied by a constitutional betterment. As to temperature, a fall may be a danger signal rather than a sign of improvement. Bennett finds an explanation of all these facts in the sensitiveness of all young patients to septic infection. In any part, therefore, where the lymphoid tissue is very abundant, as it is about the appendix, the end of which is extraordinarily well provided with adenoid tissue, we may be sure that in young and growing subjects any destructive process will often be extraordinarily acute, a fact which partly explains the peculiarity of these cases in the young. The initial changes coming on acutely in the first stage are followed so rapidly by necrosis and decomposition that the commencement of septic intoxication begins almost, as it were, before the constitution of the patient realizes the onset of the condition—in fact, at a point before the actual acute symptoms develop in an adult, the patient, if a young subject, is becoming dull and listless from the effects of the rapid absorption of septic material by the superabundant lymphoid tissue. The peculiarity of the symptoms, then, in young growing subjects, depends, first, upon the tendency to great activity in these detructive processes, and, second, to the rapid absorption of septic matter in a region supplied only too lavishly (for conditions of disease) with ready means of taking up septic material.

The Lancet, January 9, 1904.

Concurrent Urticaria and Malarial Fever.—Geo. Papakosta reports a case of this nature in a man twenty-six years of age. Coincidently with a malarial attack, in which the temperature rose to 103°, a general eruption appeared on the body, at first suggesting measles. Quinine had been taken in previous attacks and had caused hæmaturia. It was not given, therefore, in the present instance, and consequently could not be invoked as the cause of the rash. In a later paroxysm it was given but no rash appeared.

Tuberculosis of the Tonsils in Children.—L. Kingsford examined the tonsils removed post mortem from seventeen children, varying in age from four months to nine years. All showed cervical glandular enlargement, and in eleven it was obviously tuberculous. Of the seventeen, tonsillar deposits were found in seven, but only three exhibited any naked-eye tuberculous changes. Of these three, one showed ulceration, a second, scarring, and a third a caseous focus. Practically all the seventeen were cases of secondary infection from either blood or sputum. The parts of the tonsils which were the seats of the lesions were usually the lymphoid follicles not far from the epithelial surface, but it was not possible to trace bacilli in from the crypts or surface of the organs. The author believes it possible that infection may work through healthy tonsils to the cervical glands, the former becoming infected at a later period.

The Prophylactic Action of Garlic against Tuberculous Diseases.—G. Cavazzani has experimented on guinea-pigs, giving them garlic juice and then injecting dried sputum from tuberculous patients into the larynx. Control experiments were carried on at the same time, and after some weeks all the animals were killed. The results of the necropsies were that the abdominal organs and the lymphatic system of the two guinea-pigs used for control were completely filled throughout with tuberculous formations in different stages of development. The microscopical examination of some tubercles proved the presence of Koch's bacillus. In the bodies of the three animals which had been treated with garlic juice for one month from ten to twenty small tubercles were found, some of them in the liver and some in the spleen. The examination of the tubercles did not reveal the presence of Koch's elements, but instead it showed the presence of numerous fibers of young connective tissue. In the bodies of the other three guinea-pigs, those which had been treated with garlic up to the end of the experiment no tuberculous formations were found, though the most minute examination was made. The small number of animals used in the experiment forbids the drawing of conclusions.

British Medical Journal, January 2, 1904.

Note on the Method of Demonstrating Tubercle Bacilli in the Urine.—Edgar Trevithick finds that the demonstration of tubercle bacilli in tuberculous urine is more simple and certain than when occurring in the sputum. Their numbers are much greater also, in the former. The writer's method of examination is as follows: The lower part of the urine which has been resting in a conical glass is centrifugalized. The supernatant fluid is carefully decanted from the minute collection of deposit at the bottom of the glass. The glass is filled with distilled water and shaken. Again the liquid is centrifugalized and the foregoing process is repeated. From the final centrifugalate the films are prepared. The writer believes that by the ordinary method the urinary salts present both bacilli and pus cells from adhering well to the cover slip.

Reaction with Perchloride of Iron in the Urine in Grave Cases of Hepatic Cirrhosis.—F. Parkes Weber calls attention to the presence of a strong perchloride of iron reaction in the urine of several of his patients with hepatic cirrhosis. On adding a weak solution of perchloride of iron to the urine, the color obtained was sometimes similar to that obtained from the presence of diacretic acid in cases of diabetes mellitus. Sometimes, however, it appeared more like that obtained in the urine of patients taking sodium salicylate. In only one of the cases was there any history of these ever having any glycosuria. The appearance of the reaction sometimes coincided with very threatening general symptoms. The nature of this reaction has not yet been fully investigated. The writer appends the history of several cases.

A Note on Postural Albuminuria.—William H. Broadbent speaks of a group of cases in which the characteristic feature is albuminuria on rising from bed in the morning, usually passing off in the course of the day. These cases are very common, especially in boys and young men working up for examination. The albumin is not due to food. It does not appear if the patient remains in bed to breakfast or after meals later in the day. It cannot be toxæmic. It disappears quickly on lying down. It is in relation with the erect posture after a night's rest in bed, and also with imperfect cardiovascular adjustment to the changed hydrostatic conditions. The amount of albumin is generally small, but may be considerable. This form of albuminuria should be recognized, for the required treatment is just the reverse suitable in renal disease. There is commonly a neurotic family history and invariable cardiovascular instability. The pulse varies greatly in frequency and tension. A high-tension pulse would warrant suspicion of actual renal disease of or juvenile gout. The writer has observed that the impulse of the right ventricle is forcible and the apex beat weak. The second sound is reduplicated when the patient lies down. The prognosis is favorable. Usually all the treatment required is good, simple food, fresh air, and vigorous exercise. Tonics were hurtful in many cases. Constipation should be corrected by aloetic or other aperient of the tonic class.

A Clinical Lecture on Œdema of the Lungs and Its Importance as a Mode of Death.—Isambard Owen declares that the subjective symptoms of pulmonary œdema are few, and not distinctive. Distress of breathing is increased by it. Cough is often increased and becomes more hacking. Expectoration of the œdematous fluid occurs only when the œdema is extreme. Œdema has to be watched

for by regular and systematic examination of the back of the chest. Although œdema of the lungs may be checked more than once by treatment, it is usually the final scene of the drama. Œdema of cardiac origin, as it is seen in the later stages of valvular disease, begins in the most dependent parts and extends upward. This is not always the case in pneumonic œdema. The signs here may sometimes be detected in the scapular regions, or even in front as early as at the base. The writer has noted in more than one actual case of severe pneumonia that signs of œdema have begun to appear before any heart failure whatever was observable. The physician should always be on the lookout for œdema of the lungs in cases of bronchitis. When the patient's condition becomes serious, careful examination should be made to ascertain whether there may not be some condition involved that admits of treatment. In many severe cases of pneumonia, fear of cardiac failure deters the physician from a sufficiently systematic examination of the back. The writer believes that œdema is the most serious danger to life. As to the treatment, the writer states that expectorants are useless. The right side of the heart should be carefully investigated. It is even more important to note the presence of any obstruction of the venous circulation. If these signs are present and the conditions urgent, venesection should be practised. The relief from this treatment is often very marked. Other methods of treatment, less efficacious, are the application of leeches to the front of the chest; watery purgation by elaterin, jalap, or gamboge. Dry cupping is sometimes recommended. Oxygen has its place. Isolated doses of alcoholic liquors, as brandy in hot water, are often of service as a temporary stimulant, but there should not be a continuous administration of alcohol. The writer has great regard for the hypodermic injection of strychnine.

British Medical Journal, January 9, 1904.

The Life-span of the Guinea-worm.—Arthur Powell gives the history of several patients infected with the guinea-worm. The great majority of worms appeared a year and two or three weeks after the date of infection. The shortest period in these cases was 345 days, the longest 435. There is often considerable fever a few days before the worm becomes palpable. Two of the writer's cases also suffered with swelling of the face and hands. This seemed independent of the situation of the parasite. The writer calls attention to the increase of eosinophiles in the blood of these patients.

Glandular Fever.—John W. Byers, in this report, states that his knowledge of glandular fever is based on thirty-three cases. The youngest child was thirteen months; the oldest case was a maid, aged twenty-five years. With the exception of this last patient and another aged twenty-one, all were children or young people under sixteen years. The onset, as a rule, was sudden. The period of incubation was from five to seven days. The symptoms were sore throat, fever, pain on one side of the neck, and tenderness on pressure. There was a swelling of the glands under and in front of the sternomastoid. In most of the cases the deep glands of the corresponding and opposite sides of the neck were swollen. There was only slight congestion in any of the throats, and in the majority it was normal. The glands affected were, as a rule, the deep set under and in front of the sternomastoid. The majority of the children were convalescent in a week. Nearly all the children in a house were attacked. No rash appeared. There were no deaths. The writer believes these cases to be examples of that acute epidemic infectious fever in which there is primary inflammation of the lymphatic glands. The poison of this fever is probably microbial. Invasion was probably through the throat. Certain atmospheric conditions may favor the growth of the infective germ.

Observations on the Pathogenesis of Gout.—Chalmers Watson describes the post-mortem appearances in the case of a fowl which died of acute gout. The synovia in some joints was of the color and consistence of cream; this readily gave the murexide reaction. A deposit of sodium urate was in some extraarticular tissues, mainly in relation to the smaller joints. There was widespread thrombosis, notably in the vessels of the liver, lungs, kidneys, and some larger abdominal veins. Thrombosis appeared to be the immediate cause of death. There was marked congestion of the liver, lungs, and kidney. Some liver cells were atrophied. The kidneys showed areas of necrosis. It was a typical case of gout. There was no condition to indicate chronic disease of any kind. The blood-vessels were singularly healthy. There was catarrh of the intestines. The capillaries were markedly dilated. There was a great excess of lymphoid tissue in the ileum. The pancreatic duct was filled by catarrhal products derived from their lining membrane. The spleen showed congestion. The condition of the pancreatic duct appeared to be an extension from the duodenum. It was very striking. The collecting tubules were everywhere markedly dilated and filled with granular leucocytes. There were also granular leucocytes lying free in the intertubular tissue. There was an atrophy of the epithelial lining of the convoluted tubules. The writer believes that the clinical features of gout—regular or irregular, acute or chronic—are more adequately explained by the light of our present knowledge of infections, relapses, and immunity, than by any other theory. The distinctive feature of the infection in gout is that the toxin or toxins have the special property of disturbing nitrogenous metabolism in a manner favorable to the deposit of uric acid in certain tissues. The addition of a bacterial factor to our present conception of the disease would in no way minimize the importance of attention to dietetics in its treatment. It would correct the teaching of some writers whose standard of dietary has special reference to nuclein-holding foods, and would focus attention on the by-products of deranged digestion of carbohydrates and proteids arising from abnormal bacterial activity in the digestive tract and other tissues.

Münchener medicinische Wochenschrift, December 29, 1903.

A Case of Primary Actinomycosis of the Skin.—Dreyfus describes a case of this unusual form of actinomycosis occurring in a boy of ten. The lesion first showed itself as a swelling in the left mammary region, which, six months later, broke down and ulcerated. It was surrounded by a wide area of ulceration, but glandular enlargement was absent. Excision was followed by recurrence.

The Occurrence of More than One Tænia Saginata in the Same Person.—Riehl says that it is extremely rare for more than one beef tapeworm to be found in the same person, though such cases are on record. His patient was readily relieved of a tapeworm by the use of male fern, but soon after began to pass more links, although the head of the first worm had been found. A second dose of the anthelmintic produced a second head.

The Significance of the Normal Intestinal Bacteria.—Strasburger says that the bacterial flora of the human intestine normally serves a useful purpose, but may also become a source of noxious products. The question of whether animal life is possible with a sterile intestinal tract is still undecided. Nutall and Thierfelder were able to cause an increase in weight in the guinea-pigs they kept sterile from birth, but Schottelius reached opposite conclusions with chicks. It is quite possible that the cellulose envelopes of many sorts of vegetable foods require bacterial agencies for their destruction, as no cellulose dissolving ferment is found in man or most warm-blooded animals. An important function of the intestinal bacteria is probably the prevention of putrefaction in the small intestine. Corroboration of this view is found in the fact that when sterile milk is given, putrefaction occurs in the small intestine, whereas in the presence of the bacillus coli communis and the bacillus lactis aerogenes putrefaction does not extend beyond the ileocæcal valve and only fermentative changes take place in the intestine above. When the bacterial growth becomes excessive, however, it injures the body not only through the amount of nitrogenous material consumed in this way, but also through the absorption of injurious substances that are products of the organisms. The middle ground between excess and deficiency of bacteria is therefore necessary for normal conditions in the intestinal tract.

French and Italian Journals

Neoplasm of the Breast; Acetonuria.—Patel has had under his care a patient afflicted with a growth in the left breast. It has increased rapidly with metastases in the axillary and subclavicular regions. The metastasis in the spinal cord was apparent from violent lumbar pains and prickings in the leg. Intravenous injections of quinine were begun. Acetone was observed in the urine of the patient. This phenomenon has been noted in other cancerous cases. The case is inoperable, as to the mammary lesions, but it is hoped that a tuboovarian castration will arrest or retard the course of the growth.—*Lyon Médical*, December 6, 1903.

The Action of the Nuclein of Pathogenic and Non-Pathogenic Bacteria, or the Bacterial Power of Normal Blood Serum.—Domenico Enea concludes from his experimentation that the nucleus extracted from pathogenic or non-pathogenic bacteria when introduced into the circulation causes an increase of the normal bacterical powers of the blood serum. It is not specific, for the species of bacteria from which the nuclei was taken, and the difference found on the intensity of its action against various forms of bacteria is due to the different powers of resistance possessed by them. This increased bactericidal power is temporary, disappearing, after a few days.—*La Riforma Medica*, November 25, 1903.

Book Reviews.

PSYCHO-THERAPY IN THE PRACTICE OF MEDICINE AND SURGERY. By SHELDON LEAVITT, M.D. Chicago: Garner-Taylor Press, 1903.

HOWEVER much or however little store he may set upon suggestive therapy, the reader of this book cannot fail to be impressed by the earnestness of the author and his unmistakable faith in the value of this method as a means for the treatment of disease. Dr. Leavitt believes that regular medicine is doing itself and humanity an injustice in neglecting a systematic use of psychic means of cure, and in this work he calls upon the profession to rescue from charlatans, "healers," "scientists," *et id genus omne*, what he regards as a most valuable therapeutic adjuvant, supplementing and in some instances doing away with drug treatment. All thinking and observing physicians of the present day admit the efficacy of suggestion or autosuggestion in certain cases, but they also believe that this force can influence the body to only a limited degree. Dr. Leavitt on the contrary seems inclined to put almost no bounds upon its powers. That is, however, the common fault of the enthusiast, and we are sure the author makes no claims which he does not believe he can substantiate. The book will well repay study, and we are convinced that the careful reader of it will find some of his prejudices against psychotherapy softened even if he does not become a partial convert.

THE WORTH OF WORDS. By Dr. RALCY HUSTED BELL. With an introduction by Dr. WILLIAM COLBY COOPER. Third edition. Revised and enlarged. New York: Hinds & Noble, 1903.

THERE is much that is suggestive in this scholarly book, not a little that is instructive, and a few things that are misleading. The work is a series of short disquisitions or dogmatic assertions on various words and their uses. The several chapters are on "Misused Words, Vulgarisms, and 'Words-no-Words,'" whatever that may mean, "Every-day Errors," "Slang," and "How Word-meanings Change." There is nothing easier for a critic than to criticise, especially when the book under review is one which aims to set up rules for the guidance of the ignorant or the careless in manners, morals, or speech. Dr. Bell falls at times into a common error of writers on the use of correct language in assuming that a living tongue, and English of all tongues, is a thing of rules, like Volapük, or Esperanto, or even Latin, and incapable of growth or variation, and he occasionally dogmatically condemns usages sanctioned by masters of English composition. But in these days of newspaperese one should be chary in finding fault with conservatism. The new words and new uses of words will establish themselves quickly enough, and if they are legitimate their right to recognition will be all the stronger if their first advances have been opposed by those who would shield their beloved mother speech from the mutilating and deforming touch of barbarism. Dr. Bell's book is one to be read and reread by all who love good English and strive to use it in their conversation. Writers especially will find the work serviceable not only for what it contains, but also for the habit, which its study will promote, of looking at words with a critical eye, and so of employing them with greater care and discrimination.

HANDBOOK OF DISEASES OF THE EAR, for the Use of Students and Practitioners. By RICHARD LAKE, F.R.C.S., Surgeon Royal Ear Hospital, etc. With Three Colored Plates. New York: William Wood & Co., 1903.

IN twelve chapters the well-known English otologist covers the principal points of ear disease. The matter is well arranged, the type clear and the illustrations good. Scattered through the paper are many statements based on the author's extensive clinical experience and they attest the careful observer and practical teacher. One chapter of especial interest to practitioners is that entitled "Life Assurance," in which the author discusses the relations of deafness, vertigo, tinnitus, and middle-ear suppuration to the question of insurance. A deaf man is not a first-class risk. Vertigo calls for increased premiums, and if associated with Ménière's disease, for probable rejection. Tinnitus is of importance only when the applicant is of a neurotic temperament. Intolerable tinnitus may lead to suicide, and tinnitus assuming the form of voices may signify the onset of insanity. Suppuration, followed by complete recovery, does not invalidate the risk. If there has been no discharge for five years, the risk is still good, but any deviation from this standard begins to call for increased premiums. The book closes with a complete formulary and a good index.

DE LA DÉGÉNÉRESCENCE CANCEREUSE DE L'ULCÈRE DE L'ESTOMAC. PAR Le Dr. C. AUDISTÈRE. Paris: G. Naud, 1903.

IN this monograph on "Cancerization of ulcer of the stomach," Audistère has compiled the literature of the subject and added several observations of his own. The development of cancer in ulcer of the stomach does not appear to be so very rare. Usually ulcers of very long standing and situated principally near the pylorus are more apt to undergo the cancerous change. Even after the development of the cancer the symptoms of ulcer as a rule persist. This makes the diagnosis in a number of cases quite difficult, excepting in those in which a tumor can be palpated. The course of these cases is much severer and more rapid than of simple cancer of the stomach. Hemorrhages and perforations are frequently encountered and often prove fatal. This work of Audistère can be highly recommended for its thoroughness in the treatment of the subject.

THE ART OF CROSS-EXAMINATION. By FRANCIS L. WELLMAN of the New York Bar. With the Cross-Examination of Important Witnesses in Some Celebrated Cases. New York: The Macmillan Company, 1903.

THOSE medical men who have survived the horrors of a cross-examination by the author of this work must derive satisfaction from the fact that others besides themselves have been on the rack. If they have not had this experience, they will certainly at least enjoy the bright anecdotes and pleasant style of the writer, who is a past-master in the art of extorting evidence. Mr. Wellman is one of the very few lawyers who are equipped in medicine as well as their own profession, and the present volume contains references to many notable medical cases.

If any further criticism were needed, it would be that he has neglected to publish the cases in which the doctor on the stand has got the best of the lawyer, but this can hardly be expected. The work teaches among other things that even the most conscientious physician has no place on the witness stand unless he is able to take care of himself, and a man may be an expert in every sense of the word, and still lack utterly in his ability to maintain his position in court.

DISEASES OF THE HORSE, A Special Report by Drs. PEARSON, MICHENER, LAW, HARBAUGH, TRUMBOWER, LIAUTARD, HOLCOMBE, HUIDEKOPER, STILES, and ADAMS. Revised Edition. Washington: Government Printing Office, 1903.

THIS report on diseases of the horse has been prepared evidently with great care, by a number of the most eminent members of the veterinary profession in the United States, each of the authors treating of the subject most familiar to himself and upon which consequently he could speak with the most authority. The result has been the production of a treatise upon which farmers and stockmen may rely with the greatest confidence when called upon to minister to a horse diseased in the absence of a skilled veterinarian. In this revised edition a chapter on "The Examination of a Horse," written by Dr. Leonard Pearson, has been added, and one on shoeing has been written by Dr. J. W. Adams.

The work is published under the supervision of Dr. D. E. Salmon, Chief of the Bureau of Animal Industry of the Department of Agriculture, and is issued for free distribution by members of Congress, to whom those desiring a copy of the book should apply. The Department of Agriculture, we understand, has no copies for this purpose.

MONTHS AND MOODS, A Fifteen-year Calendar Versified and Diversified. By EDWARD CURTIS. New York: The Grafton Press.

If I help you fix a day
So you fail not, nor estray,
If I bring you to a mood
Working ever for the good,
Fulfilled my end!

On your desk or boudoir-table
Then, in order serviceable
At your elbow let me lie,
For the new-come century
A ready friend!

IN the lines here quoted Dr. Curtis has prefaced this happily conceived calendar, which will do service for the first fifteen years of the new century. Under each month is a page containing the fifteen calendars followed by verses appropriate to the season. A charming book to while away the weary minutes of the patient waiting his turn for consultation with the busy doctor, or to solace the tedious hours of the fledgling doctor waiting for the call of the casual patient. And before the calendar is exhausted, may his days be so full that he needs turn to the book in the evening to clear his weary brain and soothe him preparatory to refreshing sleep!

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Eighty-fourth Regular Meeting, Held Friday, December 4, 1903.

CHARLES STEDMAN BULL, M.D., PRESIDENT, IN THE CHAIR.

A Case of Paget's Disease.—Dr. HERMANN H. BIGGS presented a man, seventy-one years old, an Italian, who came to the United States thirteen years ago. He was a laborer but had never done any work in this country on account of his age and the poor condition of his health. His family history was negative, and excepting the diseases of childhood his only illness had been an attack of kidney trouble of an indefinite kind about thirty years ago. His habits were always temperate and he gave no history of venereal disease. The patient stated that when he came to this country his legs were perfectly straight: soon after his arrival he began to suffer from pains in the knees and the joints became swollen; these symptoms were especially severe in wet weather. Subsequently, the femur, tibia, and fibula began to curve outward and forward, and he became more bow-legged year after year until it had become very difficult for him to walk. He also suffered a great deal from headache prior to his admission to Bellevue Hospital three months ago. He has had no constitutional symptoms of any moment, and a physical examination revealed nothing of any especial importance. The lungs were normal; the heart slightly enlarged. He had a large left inguinal hernia. The right malar bone was apparently thickened, and the bones of the cranium were perhaps somewhat enlarged. Dr. Biggs said there were comparatively few cases of Paget's disease or osteitis deformans, of which the patient was an example, in this country: perhaps fifteen or twenty had been reported. Nothing was known as to the etiology of the disease. It generally occurred in males during middle or later life. Constitutional symptoms were usually lacking. In some cases there was considerable pain; in others, none. The tendency of the bones to curve was due to the presence of a rarefying osteitis. It affected particularly the long bones, especially those of the lower extremity. An *x*-ray photograph of Dr. Biggs' case showed this rarefied condition in the end of the affected bones. Usually the bones of the upper extremities and the facial bones were also affected, and frequently also the ribs and the spine. The changes in these latter bones in this case were not very distinctive; the striking changes being in the bones of the lower extremities only.

Dr. FRANCIS P. KINNICUTT said that Paget's disease, of which the case shown by Dr Biggs was apparently an example, was rarely met with in this country. The majority of recorded cases were from English sources. The long bones and those of the cranium were the ones usually affected by this rarefying and deforming osteotitis, while the bones of the face escaped. The deformity of the legs was very similar to that seen in rickets, resulting from softening of the bones and a relaxation of the ligaments. Apparently nothing was known concerning the etiology of the disease. It was an interesting fact that many of the cases had been found associated with malignant tumors—carcinoma and sarcoma.

Dr. W. GILMAN THOMPSON said that an interesting feature of Dr. Biggs' case was the localization of the trouble: the preponderance of the appearances in the lower extremities. In a patient shown by Dr. V. P. Gibney, some years ago, the bones of both upper and lower extremities were affected, as was the condition in the patient so fully reported by Dr. J. C. Wilson of Philadelphia. In Dr. Biggs' case the localization was chiefly confined to the knees and feet. The patellæ were enormously enlarged transversely.

Plastic Operation for Deformity of Nose.—Dr. ROBERT F. WEIR presented a man who was admitted to the New York Hospital three years ago. He had had an epithelioma of the right side of the nose which had been treated before coming into Dr. Weir's care by means of a caustic paste, and as a result of the action of this remedy the side of the nose was laid open so that a cavity remained which was an inch and one-half long and an inch wide, extending from the ala to the eye. In order to close this, Dr. Weir dissected a flap of skin from the forehead between the eyes, and without severing its pedicle, he twisted it and carried it down over the nose. The result of the plastic operation was excellent. At the end of ten days the flap was divided at its twisted part and the frontal replaced so as to diminish materially the space left by the forehead flap, the only cosmetic defect remaining being a small depression just above the tip of the nose. This was subsequently remedied by a subcutaneous injection of softened paraffin. Dr. Weir also showed the photograph of another case in which the tip of a man's nose had been bitten off by a horse. An attempt had been made by another surgeon to close the gap with a flap taken from the cheek, but the result had not proven entirely satisfactory, the new ala being very thick. The defect was remedied very happily by taking a flap from the inside of the thickened nose and carrying it downward, so as to serve as an edge to the nostril. The formation of a satisfactory nasal edge, Dr. Weir said, he had found the most difficult part of nasal reparative work. The operator, in dealing with these cases, must adapt himself to the indications to be met: no hard and fast rules could be laid down. The speaker said he preferred the plastic method to that of skin grafts: his experience with the latter on the face had not been very satisfactory. As to the resulting color, which was impaired frequently by the thinness of the implanted layer and more particularly by the many visible veins so often found in such grafts.

Intraneural Injection of Osmic Acid for Supraorbital Tic.—By Dr. ROBERT ABBE. The patient was a young man who had already been shown at the previous meeting of the society. He was then suffering from a severe form of facial tic, limited to the supraorbital branch of the fifth nerve. Since then Dr. Abbe had operated on him as follows: Under local cocaine anæsthesia an incision was made beneath the eyebrow and all the fibers of the supraorbital nerve isolated at the supraorbital foramen. This bundle of nerve fibers was then elevated and thoroughly infiltrated with a 1½ per cent. solution of osmic acid, the slight excess being wiped up immediately after the injection. The operation caused very little pain. On the day following, the painful tic occurred about fifteen times, as compared with forty to sixty shocks daily before operation. On the second day it occurred eight times, on the third day five times, and on the fourth day three times. On the fifth and subsequent days it did not occur at all, and with the exception of a slight, passing flutter of the nerve fibers on one occasion, the patient had remained entirely free from pain since. The operation, which was done on November 4, had resulted in partial anæsthesia of the scalp, which still persisted. The cornea and conjunctiva were not affected. The patient had resumed his occupation as a clothing salesman, which the facial tic had compelled him to give up. In reply to a question as to whether the relief would be permanent, Dr. Abbe said he did not know. In some of the cases on record the pain had not returned after several years.

Dr. WEIR asked whether this method of injecting osmic acid had not been advised several years ago and fallen into disuse from the unsatisfactory results that had followed the employment.

Dr. Abbe replied that at the previous meeting Dr. M. Allen Starr mentioned a case of sciatica in which the method had been resorted to twelve years ago. Some cases had also been reported in England. The method,

he thought, should only be used in sensory nerves, as motor paralysis would be a serious sequel.

Dr. Weir said there were a number of cases of sciatica on record which were apparently cured by intraneural injections of cocaine.

Dr. Abbe said the influence of an injection of cocaine upon sciatic pain rarely lasted over half an hour—perhaps an hour.

Dr. GEORGE L. PEABODY said that in an extremely obstinate and severe case of sciatica which he saw last winter, after exhausting all the usual remedies and methods of cure, he injected two centigrams of cocaine into the spinal canal. The injection produced symptoms of cocaine poisoning which yielded immediately to a hypodermic of morphine, and after three or four hours' sleep the patient awoke entirely free from pain and remained so for at least five months, when he was lost sight of. No paralysis followed the injection. The patient gave a history of a previous attack of sciatica, for which he was treated in a hospital in the West, where nerve-stretching had been tried without relief. Dr. Peabody said he had been induced to resort to the spinal injection by the report of a favorable case in a German medical journal, which quoted a communication from Cavazzoni of Venice in the *Gazzetta degli Ospedali* (Milan) May 4-18, 1902. His attention had been attracted to the subject by Dr. Foster, one of the present house staff of the New York Hospital; in that instance, the relief was said to be permanent.

Dr. CHARLES L. DANA said the injection of cocaine solution into the spinal canal for sciatica had as a rule only given temporary relief. It had also been resorted to in tabetic cases to relieve the pains. In the case reported by Dr. Peabody the patient was perhaps "ripe" for a cure when the injection was given.

The Use of Lumbar Puncture in Medical Diagnosis.—By Dr. CHARLES L. DANA. (See page 121.)

Dr. VIRGIL P. GIBNEY said that for the purpose of rendering lumbar puncture painless he had employed methyl chloride with very satisfactory results. When the parts were frozen by this method, quite a large-sized needle could be introduced, both in children and adults, with very little pain.

Dr. E. G. JANEWAY said he had not been inclined to resort to lumbar puncture to any great extent for diagnostic purposes, and he thought the knowledge gained by it could usually be obtained by other means. The procedure was comparatively simple and thus far no bad results had been recorded from its use. In France it was done very freely. Dr. Janeway said he had resorted to it for therapeutic more than for diagnostic purposes, and he was not prepared to admit that it should be adopted as a systematic procedure. The information gained by it could not always be absolutely relied upon.

Dr. KINNICUTT said that while the value of cytodiagnosis by lumbar puncture in the class of cases mentioned in Dr. Dana's paper was still *sub judice*, lumbar puncture for certain diagnostic and therapeutic purposes must be admitted to be of great value. It was commonly practised under his direction in the wards of the Presbyterian Hospital, and definite observation which could be secured in no other way was obtained by it, in addition to the relief that occasionally followed the withdrawal of a certain amount of fluid from the spinal canal.

As an interesting illustration of the practical diagnostic and prognostic value of the method, Dr. Kinnicutt said that three cases of meningitis were recently admitted into his wards in the hospital, and it was utterly impossible to classify them by the ordinary methods. In all three the symptoms of cerebrospinal meningitis were present. Lumbar puncture was done in each case, with the following results: In the first case a pure culture of diplococcus intracellularis was obtained; in the second case a pure streptococcus culture was found; while the third culture proved sterile. In the first case, although the patient was apparently in a desperate condition, remaining comatose for five or six days, a possible recovery was predicted upon the strength of the bacteriological examination, and the patient eventually did recover. In the second case, although the patient's condition did not appear to be as serious as that of the first, a positively unfavorable prognosis was given. The third case was regarded as tuberculous, and a similar unfavorable prognosis was made. The diagnosis was subsequently verified at autopsy. The second case also proved fatal and the autopsy confirmed the diagnosis. In all three of these cases an exact clinical diagnosis could not have been made in any other way than by lumbar puncture.

The speaker had never seen any evil results follow the procedure. He mentioned a case of cerebral hemorrhage, with enormously increased blood-pressure, in which lumbar puncture resulted in the withdrawal of a bloody fluid and temporary decrease in the blood-pressure and an improvement in the symptoms.

Dr. M. ALLEN STARR said while he believed that lumbar puncture possessed considerable value in a certain class of cases, he had been rather reluctant to resort to it. In looking up the literature six or eight months ago he found a very valuable paper by Dr. Blumer of the Butler Hospital for the Insane in Providence. In that paper the writer stated that in the cerebrospinal fluid of paretics, the number of cells was increased, ranging from 80 to 123 to the cubic centimeter, and he regarded this as a very valuable diagnostic point in the early stages of paresis, when it was often difficult to differentiate that disease from neurasthenia.

Dr. WEIR said the alarming symptoms that occasionally followed spinal cocainization had been attributed by some surgeons to the increase of pressure produced by the injection, and in order to obviate their occurrence it had been advised that a syringeful of cerebrospinal fluid be withdrawn before introducing the cocaine. Others had attributed the bad effects to the cocaine itself, which, in their judgment, was the more correct view. In speaking of the loss of cerebrospinal fluid, Dr. Weir said he had often wondered how great a loss of that fluid could be tolerated. It sometimes escaped freely in various forms of fracture of the skull, and unless infection subsequently occurred, he had never seen much damage result from such a leakage. Very recently he had had a case of fracture at the base of the skull, and together with other characteristic symptoms there was an oozing of clear serum from the left ear, which continued for six days, amounting, it was estimated, to from ten to twelve ounces per day. The fluid was not analyzed. The only symptom complained of was a slight headache. The patient recovered without any permanent effects.

Dr. Starr, in support of Dr. Weir's statement, referred to two cases of operation for brain tumor in the service of Dr. McCosh at the Presbyterian Hospital. In the first case, from the date of the operation to the time of the man's death, which occurred about four months later there was a constant drainage of cerebrospinal fluid, which was estimated and practically proved to be about sixty ounces per day. In the other case, the patient lived five months after the operation, and during that time there was a daily drainage of cerebrospinal fluid of about forty ounces per day. In neither case was the cerebral tumor located. In fractures of the base involving the ethmoidal sinus there was sometimes a free escape of cerebrospinal fluid through the nose. Very little was known about the physiology of the fluid. Was it constantly being secreted and in active circulation in the brain, or did this only occur after an injury?

Dr. Peabody said that in his general hospital practice he had limited lumbar puncture largely to cases of suspected tuberculous meningitis. The insertion of the needle was at times so painful, however, that he formerly had the patient lightly chloroformed before resorting to it. He now used cocaine locally, which seemed to deaden the

sensibilities down to the spinal canal. The only pain complained of was when the needle struck the periosteum. Dr. Beverley Robinson had recently called his attention to an article that appeared in the *British Medical Journal* last October in which the writer recommended the use of this procedure in cases of well-developed uræmic coma, basing his recommendation on the old theory that the symptoms were due to pressure, as indicated by the preceding headache. The writer reported two cases in which he tapped the spinal canal after the usual methods of depletion had failed to give any relief. He withdrew something less than an ounce of fluid in each case, and in both the symptoms cleared up immediately. In one of them—a case of acute Bright's—the man was practically well when he left the hospital. Since reading this article, Dr. Peabody said, he had had an opportunity to try the method in two cases of uræmic coma, one a boy of twenty-two, who had been operated on unsuccessfully years before for an empyema. A sinus persisted for which he had been operated on four or five times. When Dr. Peabody saw him there was considerable deformity of the left chest, and a deep sinus, which still drained pus. Subsequently, albumin and casts appeared in the urine, pointing to an amyloid kidney, and without warning the patient had a series of convulsions in quick succession. He was first given urethane, under the influence of which the convulsions diminished in frequency but did not cease. The spinal canal was then tapped and six drachms of fluid withdrawn. The convulsion ceased and the following day patient was perfectly clear and bright. The second case was one of chronic nephritis, with high arterial tension. The urine was of low specific gravity; it contained many casts and a trace of albumin. The patient was becoming comatose and an ounce and one-half of fluid was withdrawn by spinal puncture. The arterial tension was markedly diminished, but otherwise there was no improvement. The somnolence gradually increased and a fatal outcome was expected. Dr. Peabody said he was inclined to look upon the improvement after lumbar puncture in his first case as a coincidence. He had never seen any harmful result follow the operation, but he knew of an instance in which the needle was broken and had to be dissected out.

Dr. Joseph D. Bryant said that the plugging of the needle which Dr. Dana had encountered in some of his cases of lumbar puncture was probably due to the fact that he used an ordinary aspirating needle, which had an inner cutting edge. If a needle were employed with the inner edge dulled or entirely removed, especially at the throat of the implement, he believed that less difficulty would be encountered.

Dr. W. Gilman Thompson said that Dr. Dana's paper was an exceedingly valuable contribution to a subject which was still in its infancy. The value of the clinical conclusions of the method was still in doubt, and rightly so, because deductions based upon the numerical preponderance of a certain kind of white blood cell were apt to be misleading. Similar investigations in connection with pleuritic exudates had thus far proven of questionable value. This field of research was one which should not be too strictly criticised at present, but it certainly should be investigated further. It was a curious fact that so many different diseases could produce these numerical differences in the white blood cells.

Dr. Peabody said that in doing spinal puncture he had found that the easiest method was to have the patient lie down on his side, bowing the back and flexing the thighs on the abdomen. This widened the space between the vertebræ, and the needle readily entered the spinal canal, although it was not unusual to have it impinge upon the laminæ several times before it finally passed between them.

Dr. Bryant said the widest space was between the fourth and fifth lumbar vertebræ, and by bending the back, as suggested by Dr. Peabody, the needle could be readily introduced and there was less danger of injuring nerve tissue than by puncturing between the laminæ further up.

Dr. Beverley Robinson said that about two weeks ago he saw in consultation a case of uræmic dyspnœa which soon terminated fatally. In such a case, with pupillary contraction and rapidly developing œdema, the suggestion made by Dr. D. C. McVail in the *British Medical Journal*, October 24, 1903, to puncture the spinal canal might prove of considerable value.

Dr. Joseph Fraenkel said the method discussed in Dr. Dana's paper was a very recent one. From 1900 until recently it had been practised exclusively in France. The French observers (Widal, Sicard, Ravot, Marie, Guillaine, Déjerine, Babinski, Nageotte) were somewhat enthusiastic in their views regarding its value. Marie believed the lymphocytosis of the cerebrospinal fluid to be of equal diagnostic value as the pupillary and reflex phenomena, particularly in cases of tabes and general paresis. Widal formulated the following rules for the interpretation of cytodiagnostic findings: (1) Increase of lymphocytes (mononuclear), denoted tuberculous disease; (2) increase of lymphocytes (polynuclear), denoted acute infectious disease; (3) increase of epithelial cells denoted the mechanical origin of the disease. Dr. Fraenkel said that forty-four examinations of the cerebrospinal fluid made by him gave the following results: Fourteen times he obtained no fluid; this occurred at the beginning of his investigations and was apparently due to defective technique. The thirty cases in which the cerebrospinal fluid was obtained were divided thus: Seven cases of tabes; three cases of general paresis; seven cases of multiple sclerosis; two cases of brain tumor; three cases of syphilis of the nervous system; four cases of paralysis agitans; one case of poliomyelitis; three cases of neurosis. Generally, he was able to corroborate the statements made by the French observers that there was an increase of the lymphocytes in the cerebrospinal fluid in cases of syphilitic and metasyphilitic disease of the central nervous system and in cases of multiple sclerosis. Confirmatory results were also obtained by Schoenborn in his examinations made at Erb's clinic in Heidelberg. The speaker said that the untoward symptoms of lumbar puncture observed in the course of his investigations were headache and nausea lasting from one hour to three days after the operation. This occurred only in four instances and was considerably ameliorated by saline injections. In one case of suspected disease of the posterior fossa of the skull, and in which no fluid was obtained, the mere introduction of the cannula brought on a rather serious condition of collapse.

Dr. Dana, in closing, said that Babinski had recently reported the cure of a number of obstinate cases of tinnitus aurium, combined at times with vertigo, by tapping the spinal canal. Dr. Dana advised that more attention be paid to the technique of lumbar puncture; as ordinarily done, it was painful and disagreeable.

Spondylosis Rhizomelia.—Dr. Dana exhibited the spine of a case of spondylosis rhizomelia, or chronic stiffness of the spinal column. A history of the case from which the specimen was obtained appeared in the *Medical News*, November 25, 1899.

About two years after this report of the case, the patient died from an intercurrent affection. The vertebral column was removed and preserved as a separate specimen. It showed ankylosis mainly of the laminæ of the vertebræ, and, to a much less extent, of the bodies. The spine was perfectly rigid, like a single piece of bone, but was not deformed. There appeared to be a simple proliferation of bony tissue fastening together the processes, but without producing any great amount of bony hypertrophy or bony protuberances.

WESTERN SURGICAL AND GYNECOLOGICAL SOCIETY.

Thirteenth Annual Meeting, Held at Denver, Col., December 28 and 29, 1903.

(Continued from page 120.)

Intestinal Perforation in Typhoid Fever.—Dr. BYRON B. DAVIS of Omaha, Neb., referred to the statistics of Taylor, Osler, Finney, Keen, and others, and said that even under the past dilatory tactics the results had been very gratifying. The first twenty-four operations for typhoid fever reported showed six recoveries, or 25 per cent. When it was considered that a very large number of the operations thus far reported for typhoid fever had not been done until general peritonitis had been fully established, 50 per cent. of recoveries did not seem unreasonable, if operation was done before the advent of the peritonitis. The latest statistics from Johns Hopkins gave 41 per cent. of recoveries. There they were striving to operate for the perforation merely, but several cases were recorded with a fully developed peritonitis. Another point affecting the mortality was that a small per cent. of the cases dying after operation did not die from the operation *per se* or the perforation, but as a result of the general typhoid infection. The author thought such cases should not be charged against the operation. In the author's own limited experience, the most marked symptoms had been abdominal pain, localized tenderness, thoracic breathing, and muscular rigidity. Sudden decline of temperature and the phenomena of shock had not been so constant. Three cases were reported that had come under the writer's observation. The first was operated on the third day after the perforation symptoms arose, death following twenty-four hours later. The second was operated on twenty-six hours after perforation, and was followed by death in eighteen hours. The third was seen only seven hours after the perforation occurred, and there was so much doubt about the diagnosis that no operation was done. As the later history and the autopsy showed, this was the most favorable case among the three for operation, and had served to stimulate the author to a study of the subject and to revise his opinions as to the treatment of this condition. In the last case he could not help thinking that frequent estimation of the hæmoglobin and a red blood-cell count might have been of material value in differentiating between intestinal perforation and hemorrhage.

Dr. E. J. A. ROGERS of Denver, Col., said the main point to be reiterated was that if one waited for a positive diagnosis, it would be too late probably to operate. In very few cases of typhoid fever could a diagnosis of perforation be made. He mentioned an interesting case in which an operation was performed for perforation of the intestine eight hours after it occurred; but the patients survived only thirty-six hours thereafter, and died from what was thought to be general peritonitis.

Dr. VAN BUREN KNOTT of Sioux City said his experience coincided with that of the essayist. He had encountered two cases of perforation of the intestine due to typhoid fever, with two deaths. One of them came to operation eighteen hours after perforation, the other thirty.

Dr. JAMES E. MOORE of Minneapolis, Minn., mentioned a case in which operation was performed on the third day after perforation had taken place. General peritonitis was present, yet the patient recovered.

Dr. A. I. BOUFFLEUR of Chicago referred to the differential diagnosis between perforation and hemorrhage. One case operated on by him was one in which there was a difference of opinion as to whether or not hemorrhage or perforation was present. This case occurred several years ago, before the value of a blood count was emphasized. Operation was performed, and the patient recovered. The case emphasized the point that even in cases of doubt as to whether there was perforation or marked hemorrhage, operation was not necessarily fraught with serious danger.

Dr. C. H. WALLACE of St. Joseph, Mo., recalled a case that came under his observation some eight years ago, the patient having suffered from a second attack of typhoid fever. Perforation had undoubtedly occurred as the man exclaimed that he "felt something escape into the abdominal cavity." Operation was advised, but refused. An ice-bag was applied, peristalsis controlled, and although patient had pronounced shock, with localized tenderness, etc., he recovered. The speaker thought this was a case in which the localized perforation was taken care of by nature.

Dr. H. A. SIFTON of Milwaukee, Wis., had encountered two cases of perforation of the intestines from typhoid fever, when engaged in general practice. He believed that a careful examination would usually reveal perforation, and it did not seem to him that in the majority of cases it was difficult to diagnose perforation. In both of these cases the perforation was confirmed by a post-mortem examination. The first case of perforation he operated on was in 1895, the diagnosis having been made within a few hours after perforation, and the operation resulted in a recovery. The second one occurred two or three years ago, the perforation in this case having been in the appendix. This case resulted fatally.

Dr. CHARLES E. BOWERS of Wichita, Kan., emphasized the element of time in cases of perforation from typhoid fever. In searching for rupture of the intestine from typhoid fever ulcer, he said it seldom, if ever, occurred higher than three feet above the ileocæcal valve. One could shorten time very much by satisfying himself that it did not occur above that point.

Dr. H. G. WETHERILL of Denver, Col., said there had been a number of cases of perforation reported in which operation was done three days later, and other cases in which operation was not performed, with recovery. He called attention to the fact that perforation might give rise by erosion of the mucous membrane to the transmigration of bacteria through the serous coat without actual perforation, and that this condition of things was perhaps more frequent than physicians had heretofore believed. Some cases of perforation were probably of this class. Speaking of diet and the matter of treatment of typhoid fever, he thought the time was not far distant when the general practitioner would reach the conclusion which surgeons had pointed out, that a milk diet was not the best for typhoid-fever patients.

Dr. Davis, in closing the discussion, said the plea of his paper was toward early recognition of perforation and early operation.

Surgical Treatment of Nephritis.—This was the title of the President's Address, delivered by Dr. ALEXANDER HUGH FERGUSON of Chicago. Reference was made to the early history of this subject, and to the priority of the operation. The author added three cases to those he had already published of renal decapsulation and puncture for active diffuse nephritis. The indications for surgical treatment of this condition were pointed out at length and the technique of the operation fully described. In looking over the literature, the author finds that the causes of death after the operation in 123 cases, by different surgeons, were as follows: Four died of pulmonary œdema, 6 of uræmia; 4 of coma; 3 of sudden heart failure; 3 of exhaustion; and 1 each of endocarditis, suppression of urine (ether being used), anuria, general dropsy, collapse, pleuritic effusion, and myocardial thrombosis. There were 27 deaths out of 123 cases within a year after the operation. A closer analysis shows that of these deaths, 6 died within 18 hours after the operation: between one and nineteen days; 2 between two and seven weeks; 3 between two and three months; and 1 lived a year. The vast majority of these deaths should not be attributed to the operation. Even allowing all deaths within a week to be due to the operation, there would be a mortality of only about 9 per cent. When the limitations of the operation were more clearly defined, a

many of the extreme cases left alone, the author thought the mortality should not be more than 5 per cent. in the hands of experienced surgeons. It was fair to conclude that the earlier an operation was performed in these cases, the less would be the fatality, and the greater the benefits.

Multiple Loose Bodies in the Knee-joint.—Dr. JOHN P. LORD of Omaha, Neb., reported the case of a middle-aged man who had suffered from recurrent attacks of arthritis, the result of loose bodies in the knee-joint. The attacks of inflammation and the frequent incapacity resulting therefrom had driven the patient to seek operative relief. Loose bodies in the posterior part of the joint were the chief offenders, and it was thought that no ordinary incision would permit of their successful removal. The writer's attention having been called to the use of the Volkmann incision by the Mayo brothers for suppurating knee joint, it was determined that this method of attack would be required in this case. Transverse division of the patella and the incision of the lateral and crucial ligaments were therefore done, as in an operation for resection. This permitted full command of the articulation. Great difficulty was encountered in removing two of the bodies located behind the condyles. The patella was wired. The capsular ligaments were sutured with chromicized gut. Drainage was instituted and an interrupted plaster dressing applied. Union was primary, and a good result secured, although motion was limited. After two months the degree of flexion amounted to about 30 per cent. Attention was called to the necessity of delaying manipulation after this procedure for fear of retearing of the immature union of the ligaments, thus rekindling the arthritis. After a period of two months, however, active efforts were made to restore function, with greater success, although it was probable that full function could not be regained after such extensive surgical trauma of disarticulation. No precedent in literature was found for so radical an operation for this condition. There were ten of these loose bodies of large size, and so distributed that the ordinary incisions recommended would have been ineffective in securing the bodies, part of which were attached by pedicles. Less radical means would have defeated the object of the operation, and the patient's relief would not have been complete.

Chronic Adhesive Sclerosing Peritonitis.—Dr. H. G. WETHERILL of Denver read a paper on this subject, in which, after reporting an interesting case at great length, he presented the following points: (1) The rareness of the disease. (2) Failure to recognize it generally and to describe it fully on this continent, though it had been long well-known abroad. (3) The pathognomonic sign, namely inability to unite the shrinking peritoneum when once divided during the course of the operation, which, so far as the writer was aware, he was the first to observe and describe. (4) The essential chronicity of the disease, as indicated by long-standing symptoms, otherwise unexplained, and by the shrinking and retraction of the peritoneum at the first operation, sixteen months prior to the patient's death, which proved the previous existence of the malady, and that it was not directly or indirectly the result of the operation. (5) The great importance of covering all denuded surfaces when, before or during the operation, chronic adhesive sclerosing peritonitis was diagnosed. (6) The characteristic subperitoneal connective tissue hyperplasia which was the pathological feature of the disease. (7) The shrinking or contraction of the peritoneum caused by it, the clinical feature. (8) The possible significance of a somewhat similar pathological process taking place in the skin, coincident with unusual gastro-intestinal symptoms otherwise unaccounted for. (9) The danger of serious sequelæ incident to its surgical treatment. (10) The possibility of accomplishing much through medicinal measures, when the etiology of the disease was better understood. Potassium iodide and inunctions of mercury were worthy of careful consideration and trial in any suspected case of plastic peritoneal sclerosis.

Median Perineal Prostatectomy.—Dr. GEORGE E. GOODFELLOW of San Francisco, Cal., had operated by the median perineal route in cases of hypertrophy of the prostate approximately seventy-three times, without any immediate mortality, so far as he was aware. He described the technique of the operation in detail. All of these operations were done under spinal anæsthesia. Recently he had modified the operation a little. Instead of making an incision, as he had previously described in his papers, from the base of the scrotum to the margin of the anus, he now made an incision an inch in length above the perineal center, and through this opening he could enucleate the prostate with his forefinger. If it was necessary to enlarge the opening, he did so in the usual way. But through an ordinary incision he had enucleated a prostate weighing 7½ ounces. In no case had he failed to secure anæsthesia when he had entered the canal. The needle was inserted between the second and third lumbar vertebræ.

Complications and Sequelæ of Prostatectomy.—Dr. JAMES E. MOORE of Minneapolis stated that no single operator had had sufficient experience to enable him to speak authoritatively upon the subject, and such extremes of experience had been reported that it was difficult to estimate the real dangers and difficulties of prostatectomy. It was altogether too grave an operation to be resorted to as a routine treatment for enlarged prostate, and was only applicable to properly selected cases. There would always be a place for palliative measures in neglected cases of prostatic enlargement. The most frequent cause of death following this operation was uræmia, consequently the most important preliminary examinations were those of the kidneys. The next greatest danger was sepsis, and in the presence of an infected bladder it was an ever-present one. The most positive indication for operation was very often a complicating cystitis, and it was for the relief of this complication that the various palliative measures were most frequently employed. The only satisfactory treatment for this complication was drainage, and this was best brought about by perineal prostatectomy. Stone was a frequent complication of enlarged prostate, and should always be sought for and removed during the operation. The incision for a prostatectomy, when too extensive, caused various complications. Hemorrhage was an occasional complication, but its dangers had doubtless been overestimated. A serious objection to the suprapubic operation was the extensive injury done to the bladder; while the most difficult problem connected with the perineal operation was how to avoid injury to the rectum. As sequelæ of prostatectomy, he mentioned impotence and incontinence or dribbling. A communication between the urethra and the rectum was one of the sequels met with occasionally. Epididymitis was quite a common sequel of prostatectomy, sometimes becoming so troublesome as to require the removal of the epididymis. Because the writer had dwelt briefly upon possible, as well as probable, complications and sequelæ of prostatectomy, he did not wish to be classified as a pessimist. Some failures were bound to follow this important operation, as they did every operation of like magnitude. But notwithstanding this fact, it was destined to be one of the greatest boons modern surgery had to offer suffering mankind.

Dr. ALEXANDER HUGH FERGUSON congratulated Dr. Goodfellow upon his remarkable success, but thought he would yet encounter cases that would terminate fatally. Personally, the speaker had operated upon thirty-one or thirty-two patients without a death, without complications or sequelæ, but since then in operating in these cases a death would occur after every few cases. He had had four deaths, so far as he could determine, after having operated in forty cases. In only one of these was death due to the operation *per se*.

The Use of Silver Foil to Prevent Adhesions in Brain Surgery.—Dr. M. L. HARRIS of Chicago said the general principle of the introduction of some foreign substance had been tried in a sufficient number of cases of brain surgery to prevent adhesions, and with results which seemed to justify a belief in its efficacy. Of the materials thus far proposed, the author believed the thin foils were the best, and of these he preferred the silver foil. It was thin, soft, and smooth. It conformed to all irregularities of the surface on which it was laid. As many layers might be applied as necessary to secure a smooth, unbroken surface. It was not only tolerated very kindly by the tissues, but exerted a beneficial influence on granulating or healing surfaces. The foil might be placed directly in contact with the brain tissue between the pia and dura, or wherever it might be necessary to accomplish the purpose desired. The author had used the silver foil in a number of cases of brain surgery, and urged its more frequent use. He cited a case which illustrated the application of the principle.

Resection of Arteries and End-to-end Union.—Dr. O. BEVERLY CAMPBELL of St. Joseph, Mo., detailed forty experiments on animals, in which different methods of operating were adopted. The author stated that from a recognition of the probably correct theory of the coagulation of the blood, and considering the experiments that had been made and the results obtained, eliminating the process of infection, there still remained factors in the production of thrombosis in the suture of arteries yet to be met and overcome before it could be hoped to reëstablish permanently the circulation of the blood following end-to-end union of arteries. The possibilities of permanently reëstablishing the circulation of the blood in arteries following end-to-end union, or resection, was in the author's opinion yet to be demonstrated. In the experiments of Murphy, as well as the writer's, it was observed that where thrombosis did not occur, in the majority of cases an obliterating endarteritis occurred. Murphy observed: "After suture of a vessel there is a tendency to endarteritis obliterans." As this process was one of slow formation, it was one of minor importance as to the ultimate result of arterial suture. While the endarteritis was occluding the vessel, collateral circulation was being established, and the danger of death of the part obviated. The following were his conclusions—(1) The death of the endothelial cells following injury to arteries and the addition of cell death incident to the trauma inflicted from operative measures for the repair of the injury probably furnished the necessary nucleoalbumin needed for the production of the chemical process of coagulation of the blood. (2) That in the resection of arteries and in their suture in continuity, the suture should not penetrate the intima, as the additional death of endothelial cells incident to passing the suture and surrounding it from pressure necrosis might contribute to the coagulation of blood. (3) That the most rigid aseptic technique should be followed in surgical work upon the arteries.

Surgical Treatment of Pulmonary Abscess.—Dr. VAN BUREN KNOTT of Sioux City, Iowa, stated that in two cases which he had seen, although the patients presented all symptoms common to pulmonary abscess, and the physician in attendance, as well as himself, were satisfied of its existence, they were only able to locate it in one case at the autopsy, and in the other suffered the indignity of having the diagnosis confirmed and failure to locate the abscess accentuated by its rupture into the pleural cavity, with empyema as the penalty. While in many quarters attempts to locate the abscess by aspiration had been denounced as unsafe, and injudicious, his limited experience had taught him the inadvisability of attempting to open an abscess of the lung without the aspirator as a guide. The physical signs common to this condition in many cases were alone not sufficient to render its exact localization possible, and while one might be satisfied in a given case that the lung contained an abscess, and from the usual methods of examination had decided as to its location, this point should be corroborated by the aspirator before proceeding with the operation. Two cases of pulmonary abscess were reported. As to the treatment of these cases by other than surgical methods, the author said it promised little, and as the complications of gangrene, empyema, and bronchiectasis so seriously increased the mortality, even in the hands of the best operators, it would appear that a plea made for early operative relief of patients suffering with pulmonary abscess was not inconsistent with the facts.

The Anatomy and Physiology of the Peritoneum and Their Relation to the Treatment of Peritonitis.—Dr. ARTHUR E. HERTZLER of Kansas City, Mo., said the stomata were declared to be artefacts, for the reason that they occurred only when the peritoneum was treated with a silver nitrate solution. They did not appear when dilute solutions were injected into the peritoneal cavity of the living animal. Other reasons had been given in a previous paper. Attention was called to the fact that the universal reference to the deposit produced when a serous membrane was treated with silver as an albuminate of silver was an error. No such substance existed. What was formed was in all probability a silver chloride produced by the action of the chloride in the fluid with the silver. In the silver solution, producing the stable silver chloride. The peritoneum was covered by a layer of fat cells resting on a layer of elastic tissue. Below this were the blood and lymph vessels. Both systems always formed complete channels and the lymph vessels never formed a connection with the peritoneal cavity. In the process of absorption from the peritoneal cavity the fluid must pass between the endothelial cells lining the peritoneal cavity, through the elastic layer, and between the cells lining the blood-vessels. Whether the cells of each of these layers were united with the intercellular bridges could not be stated. The absorption of .7 per cent. NaCl. solution took place more rapidly than any other solution. Salt solutions of more than one per cent. were absorbed more slowly. Certain solutions caused a transudation instead of being absorbed. Chief among these was formalin. It was effective in a dilution of 1-10,000. Absorption was likewise lessened by the production of an artificial hydræmia. Saline solution might be used either by hypodermoclysis or per rectum, the former being the more rapid and certain. Applying these researches to the treatment of peritonitis, the fallacy of salt irrigations was insisted upon. By using this fluid the toxins were hurried into the circulation more rapidly. The logical treatment was to employ those means which retarded absorption. The production of an artificial hydræmia might be accomplished by the injection of the salt solution either under the skin or per rectum. Formalin in the strength indicated was safe, as had been previously determined by intravenous injections.

Cholecystitis, with Special Reference to Etiology and Diagnosis.—Dr. T. E. POTTER of St. Joseph, Mo., after reviewing the subject, said that the most probable cause of infection of the gall-bladder was not through the intestinal walls, nor through the hepatic tissue, nor from the duodenum through the hepatic ducts, but through the blood of the portal system; and from this source we not only had the catarrhal and parenchymatous inflammations, with occasional empyema, but sometimes malignancy caused by the presence of stones. Among the most prominent symptoms he mentioned tenderness immediately under the ninth intercostal cartilage, saying that this symptom was as valuable as tenderness in the region of McBurney's point in cases of appendicitis. This tenderness might extend down for two or three inches. To elicit it, one should press the fingers up under the ribs and require the patient to take a deep respiration. The patient would complain of pain, and if the fingers were held firmly, the act of inspiration was in-

stantly stopped as though there had been a sudden attack of pleurisy.

Treatment of Posterior Perforations of the Fixed Portions of the Duodenum.—Dr. J. E. Summers, Jr., of Omaha, Neb., read a paper on this subject. Retroperitoneal perforations of the duodenum were of such infrequent occurrence that little attention had been directed toward their treatment. After a careful study, he had been unable to find anything written upon the subject that was at all satisfactory. After referring to the surgical work of Kocher, Villard, Jaboulay, Henle, Jeannel, and Mikulicz, the author reported a case of gunshot wound involving the anterior wall of the upper vertical portion of the duodenum and the posterior wall of the duodenum nearer the lower angle. A young man, in attempting to escape from a policeman, was shot in the back by a 38 calibre Colt's revolver, the ball entering one inch below the twelfth rib and through the outer edge of the erector spinæ muscles, coming out in front one and one-half inches below the juncture of the ninth right costal cartilage, with the right rectus muscle. One hour after the shooting the patient was etherized; the abdomen was opened by a vertical incision through the wound of exit. It was observed that the bullet had in its course from behind forward perforated the duodenum and gall-bladder. The wound in the anterior duodenal wall was sutured, likewise both holes in the gall-bladder. Because of the bad condition of the patient, it was decided not to attempt to expose the posterior duodenal wall from in front, but rather to rely temporarily upon an incision from behind, and the introduction of the gauze pack. In the carrying out of this latter procedure the writer discovered that the bullet had made a groove through the lower pole of the right kidney, another reason for the posterior incision. A liberal gauze pack drain was introduced down to the repaired duodenal wound of exit, and the wounds of the gall-bladder, and the abdomen closed so as to admit of the drainage. The patient died three days later, the post-mortem illustrating the cause of death to be a retroperitoneal phlegmonous inflammation without peritonitis. Had the man's condition permitted, the author would have sutured the wound in the posterior duodenal wall after freeing and rotating the duodenum to the left. In the light of to-day one should, in a like case, in addition to repairing the duodenal wound or wounds, occlude the pylorus by means of a purse-string stitch. Either at this same operation or as soon thereafter as reaction permitted, a gastroenterostomy should be made. None of the procedures which he had indicated required much time for handling of the intraabdominal contents. They were the only rational methods of treating a perforation of the posterior wall of the duodenum. It was almost impossible for a gunshot wound of either the stomach or duodenum, which perforated both walls, to be limited to those organs. Therefore, under such circumstances, in addition to the repair of any intraperitoneal organs involved, proper incisions must be made to provide for retroperitoneal drainage.

Election of Officers.—The following officers were elected: *President*, Dr. Charles H. Mayo, Rochester, Minn.; *First Vice-President*, Dr. H. D. Niles, Salt Lake City, Utah; *Second Vice-President*, Dr. L. L. McArthur, Chicago; *Secretary-Treasurer*, Dr. B. B. Davis, Omaha, Neb.

Milwaukee, Wis., was selected as the place for holding the next annual meeting; time December 27 and 28, 1904.

Scarlatina.—Tobeitz, to prevent or cure nephritis, injects 1 c.c. of oil of turpentine into the outer aspect of the thigh and two days later give 25 drops by the mouth in capsule or emulsion. In severe cases he repeats the operation on opposite thighs on successive days.—*Medical Times and Hospital Gazette.*

New Instruments.

A MODIFIED ALLIS INHALER.*

By A. F. ERDMANN, A.B., M.D.,
BROOKLYN, N. Y.

THIS modification is an attempt to make still more serviceable an instrument whose value is most highly appreciated by American anæsthetists. One wishes another inhaler were at hand only when it becomes necessary to turn the head of the patient from the vertical to a more or entirely horizontal plane, for it is decidedly inconvenient to drop ether upon an Allis inhaler when the head is turned far to one side. The Sim's was Skene's favorite position for most vaginal operations, and when I began my anæsthetic service with him I soon wanted either to put aside my Allis, or else modify it to fit my needs. It was in 1898 that I hit upon the idea since then so excellently introduced in the Fowler inhaler, of making the inhaler to open on the side instead of at the top. As I have shown in an old model, this can easily be done by simply cutting out of the rubber cover a half-inch strip across its middle third about three and a half to four and a half inches from the lower edge, and shutting off the air supply from above by merely stuffing in a towel or laying over the metal frame a tight-fitting piece of rubber or sheet metal.

The inhaler can now be used in either way. A towel or bandage pinned around will close the lateral opening, leaving a plain Allis; the side slit can be quickly exposed and the top opening covered to adapt the inhaler for side positions. To be sure this new procedure greatly diminishes the open-air

The Modified Allis Inhaler.—A, B, metal frame. C, side plate pushed back to open fenestra; dotted outline shows it full size and shape closing the opening. D, top plate, with open knob, to fit snugly over metal frame.

space, but not so much as to be of practical interference. Besides, more air, as much as is desired, can be admitted by tilting the upper plate or laying the towel in loosely. When the inhaler is entirely closed it is adapted for the exhibition of ethyl chloride by the German method, and for the use of the bromide of ethyl according to Fowler's directions.

*Presented before the semi-annual meeting of the Medical Society of the State of New York, held in New York October, 1903.

My experience during the past five years has confirmed my opinion as to the utility of this modification, and I now pass the suggestion on that it may be used for what it is worth. Tieman makes the instrument with a reinforced fenestrum, and furnishes two plates with handles. The knob on the side plate is purposely placed eccentrically that the slit may readily be wholly or only partly opened or closed.

The advantages are:

1. The inhaler can now be used in either the vertical or a side position of the head.

2. The inhaler can quickly be converted into either an open or a closed form.

3. The inhaler is adapted equally well for the exhibition of ether, the solutions on the Schleich principle, and for the more fugacious agents.

Since the foregoing was written it has seemed feasible to modify the inhaler further so as to permit the use of both oxygen and nitrous oxide gas. For the former it was necessary only to make the knob on the upper plate patulous: the tube from an oxygen tank can easily be slipped over the knob at any time in the course of the administration and as much oxygen be given as is desired. But this simple method is not sufficiently efficient for the economical use of nitrous oxide. However, the writer hopes to be able shortly to perfect this feature also, and to present an inhaler which, by slight manipulations, is adapted for all anæsthetic agents.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 16, 1904:

	Cases.	Deaths.
Measles	878	21
Diphtheria and croup	425	59
Scarlet fever	365	21
Smallpox	...	...
Varicella	181	...
Tuberculosis	348	186
Typhoid fever	29	8
Cerebrospinal meningitis	...	7

The Actions of Certain Agents upon the Animal Heat Mechanism, with Especial Reference to Morphine.—Edward T. Reichert concludes from the results of his researches: (1) That morphine exerts coincidently thermodepressor and thermoaugmentor actions, the former being by far the more important; and that the thermodepressor effects may be preceded or interrupted by thermoaugmentor effects. (2) That the thermodepressor action is exerted, practically, solely upon the caudate thermoaugmentor center. (3) That the thermoaugmentor action is exerted chiefly upon the pontobulbar thermoaugmentor center, and to a very limited extent upon the skeletal muscles. (4) That morphine and cocaine are direct antagonists in their actions upon the caudate center.—*University of Pennsylvania Medical Bulletin.*

The Rôle of the Abdominal Muscles in Relation to Hernia.—J. W. Dowden says that, apart from the all-important state of asepsis, there are two factors which greatly conduce to the successful issue of an operation as far as hernia is concerned, and these are the presence of strong abdominal walls, and the freedom of these walls from fat. The advantage gained by the presence of well-developed abdominal muscles is two-fold—first, there are strong, healthy structures to bring into apposition, and second, any orifices that may exist in them are reduced in size by the contraction of these muscles. A lax abdomen should be strengthened for a month or more before operation is undertaken, or if any emergency arise, and an operation has to be performed, exercises ought to be initiated a week to ten days after the event. The abdomen must be "pulled in" as flat as possible, and this tonic contraction maintained as long as possible. In addition to this, which is the best and the only suitable form for immediate post-operative treatment, other exercises may be employed, such as stooping and bending with stiff knees, lying on the floor with the feet fixed against something solid, and slowly raising the body to the sitting posture and slowly resuming the horizontal. It is astonishing how much can be done in reducing the abdominal girth, especially by the operation of pulling in the abdomen.—*The Scottish Medical and Surgical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended January 16, 1904:

THE MOVEMENT OF PLAGUE IN THE PHILIPPINE ISLANDS.

By E. L. MUNSON, M.D.,

CAPTAIN AND ASSISTANT SURGEON U. S. ARMY, ACTING COMMISSIONER OF PUBLIC HEALTH FOR THE PHILIPPINE ISLANDS.

SINCE the appearance of the first recognized case of bubonic plague in Manila, from January 1, 1900, to September 1, 1903, there have occurred 970 cases of this disease with 812 deaths, giving a total case mortality of 83.8 per cent. for the outbreaks occurring in the four successive years. Of the above totals, 198 cases with 166 deaths have occurred during the twelve months prior to September 1, 1903, giving a general case mortality for this period also of 83.8 per cent. This case mortality is less than that in Hongkong, in which the rate during the past year has been 87.6 per cent.

The city of Manila appears at the present time to be the only place in the Islands in which plague has gained a permanent foothold. It is true that a few cases have developed outside of Manila, but, so far as known, with but one exception, all the persons so affected had lately been in that city, and had presumably acquired their infection there. There seems to have been no spread of the disease from these persons to those with whom they came into contact. During the four years, thirty-four cases of plague, with twenty-seven deaths—and in the past year, three cases with three deaths—have occurred in transients while on a visit to Manila, nearly all of these persons being from small towns in the vicinity.

Why the disease has not been widely transported from Manila to various other points in the Islands by plague rats is probably due to the fact that cascos, bancas, and lorchas afford no secure retreats in which rats can hide, and the small inter-island steamers tying in the river here are nearly always required to take on and discharge cargo at other ports by means of open lighters, while lying well off shore. It is difficult for rats to spread the disease from Manila by land, as the opportunity for their transportation by rail or vehicle is practically nil, and the numerous canals in and around the city, together with the fact that the latter is practically surrounded by low lands and rice fields which are flooded during a large part of the year, offer few opportunities for the natural migration of rodents. For these reasons, if the inter-island boats are occasionally fumigated to kill the rats thereon, it would seem as if there should be little likelihood of other parts of the islands becoming infected; while if the steamers from China and plague-infected ports are watched, kept out in the bay, unless fumigated and their Chinese passengers subjected to preventive inoculation, there should be little opportunity for new infections to be introduced into the city from the Asian mainland, as has been undoubtedly the case from time to time in the past. If then there remains but one main focus of infection in the islands which can be kept from receiving new injections from outside it should be possible to ultimately exterminate the plague infection by comprehensive sanitary measures, the expenditure of sufficient funds, and the exercise of much discretion and patience. This extermination, however, is not to be regarded as a simple matter. Plague infection is extremely insidious, and sporadic cases develop every now and then, in communities from which it had been thought that the disease had been exterminated. This tendency on the part of plague has frequently led to premature belief that its infection had been eradicted, as was the case in 1902, in Manila, Yokohama, Honolulu, and in various cities of Australia, where, as a matter of fact, the infection had simply been so reduced and controlled that its active existence had been converted into a condition of latency. For this reason, it is important to remember that while proper measures may exert a prompt effect upon the prevalence of the disease, it will not do to relax the precautions needful merely because the disease is greatly diminished as to the number of cases—or even if a case has not developed for six months. A proper time test of the eradication of the existing plague infection from the city of Manila should be regarded as twelve consecutive months, during which period not a case of the disease has occurred among human beings nor a plague-infected rat found.

The cases of plague occurring in Manila from January 1, 1900, to September 1, 1903, have been distributed through the city by districts as follows:

CITY DISTRICT.	TOTAL POPULATION OF DISTRICT CENSUS OF 1903.	CHINESE POPULATION OF DISTRICT CENSUS OF 1903.	PLAGUE CASES IN DISTRICT.	PLAGUE CASES PER 1,000 POPULATION.
San Nicolas	29,059	7,225	312	10.73
Binondo	16,613	6,386	239	13.79
Tondo	37,889	934	140	3.69
Santa Cruz	35,040	3,690	88	2.51
Intramuros	11,463	559	74	6.45
Quiapo	11,149	290	47	4.22
San Miguel	8,838	693	10	1.13
Sampaloc	18,779	347	11	0.59
Malate	8,858	122	4	0.45
Paco	6,725	151	5	0.74
Ermita	12,226	631	3	0.25
Pandacan	2,990	48	3	1.0
Santa Ana	3,255	27	0	.0

From the above figures it is evident that plague has been very closely restricted to certain quarters of the ciy, and chiefly to those quarters in which the Chinese population is relatively large. The districts which have been especially infected are also those in which the poorer and less intelligent classes live and where there is the greatest degree of overcrowding, both of buildings with respect to each other and of persons within them. The disease has especially prevailed along the waterfront, and in the congested mercantile districts, where it evidently secured its first foothold. The buildings in these districts are largely of old Spanish construction, poorly ventilated, insufficiently lighted and generally insanitary. They afford innumerable retreats and runs for rats, from which these cannot be readily dislodged, and when once infected with plague their disinfection becomes a matter of very great difficulty.

As a rule, it is in the most insanitary buildings that the plague cases occur.

During the twelve months prior to September 1, 1903, the cases of plague were distributed throughout the city, by districts as follows:

CITY DISTRICT.	NUMBER OF CASES.
San Nicolas	50
Binondo	42
Tondo	28
Santa Cruz	32
Quiapo	22
Intramuros	8
San Miguel	5
Ermita	3
Sampaloc	3
Malate	1
Pandacan	1

This distribution varies, on the whole, but little from the general distribution of the disease for the entire period of its existence, as shown in the previous table. The plague situation in the Walled City has been much improved, while that for Quiapo district has lately become somewhat less satisfactory. Conditions in the remaining districts have remained practically unchanged. It is possible that all the districts in the city are infected, but, if so, this is certainly the case with regard to portions of the city to only a relatively slight degree. Obviously the plague infection has been practically unable to spread among human beings in certain districts, and it seems, indeed, to maintain its very existence with much difficulty in certain parts of the city. With abundant opportunity at hand for transmission of the infection by human beings and migrating plague rats, there is nothing to have prevented these districts from becoming plague centers, except local conditions and the character, class, and mode of life of the inhabitants. Reasoning from the past, the probability of their becoming seriously infected in the future seems therefore not to be great. Certain parts of Manila may thus practically be disregarded in the application of special preventive measures against plague, with the expectation that if the plague infection can be exterminated by vigorous efforts in such districts as San Nicolas and Binondo it will simultaneously cease to exist in Ermita, Malate, San Miguel, and other sections of the town, as a result of these latter districts no longer being able to acquire new sporadic infections from time to time from the quarters of the city in which the disease has endemically prevailed. The sanitary work against plague, now being carried on, and projected for the future, is based on the fact that plague in Manila seems to be a disease of restricted locality, from which it is apparently able to extend and perpetuate itself only with considerable difficulty. It would appear the part of wisdom, therefore, to concentrate every energy upon the extermination of plague infection from those districts in which the disease has unquestionably secured a permanent foothold.

Using the census figures for 1903 as a basis of estimation, it is seen that from January 1, 1900, to September 1, 1903, the various classes of the population, not including American soldiers, have furnished plague cases in the following proportion by race:

RACE.	NUMBER OF PERSONS, CENSUS OF 1903.	NUMBER OF PLAGUE CASES.	NUMBER OF PLAGUE CASES PER 1,000 POPULATION.
Americans	4,389	6	1.3
Europeans	3,645	6	1.6
Chinese	21,230	578	27.2
Filipinos	189,782	379	2.0
All others	895	1	1.1
Total	219,041	970	4.4

These figures show the disproportionately great susceptibility of the Chinese population to the disease; it occurring relatively about twelve times more frequently among Chinese than among Filipinos and about twenty times more frequently than among Americans. As far as Manila is concerned, plague may, therefore, almost be regarded as a Chinese disease. Similar figures are found in every plague-infected town in which a white and Chinese population co-exist. In San Francisco it is understood that ninety-two consecutive cases of plague occurred among Chinese, with not a single case among whites. In Hongkong, the Chinese population has suffered in respect to the disease to a disproportionately great extent. It is rational to conclude, therefore, that in Manila any special efforts against the disease must be made to apply first of all to the Chinese.

The case mortality of plague for the total period, January 1, 1900, to September, 1 1903, was influenced by race as follows:

RACE.	NUMBER OF CASES.	NUMBER OF DEATHS.	CASE MORTALITY, PER CENT.
Americans	6	4	66.6
Europeans	6	6	100.00
Chinese	578	513	88.7
Filipinos	379	288	75.9
Others	1	1	100.00

These figures show that not only are the Chinese very much more liable to contract plague than are the Americans or Philipinos, but if they do contract it they are far more liable to die from the disease. This experience in Manila is borne out in the epidemics elsewhere, where the relatively slight vital resistance of the Chinese against plague has always been apparent. Thus in Hongkong, during the present year, of 1279 Chinese attacked 1183 died, or 92.4 per cent.; of 84 other Asiatics, 39, or 46.3 per cent., died; while of 36 Europeans but 4, or 11.1 per cent., succumbed. The difference in racial susceptibility to plague and in vital resistance to the disease when once developed, as shown by the above figures, is very striking.

The classification of the plague cases by age cannot be carried out except for the twelve months past, as prior to September 1, 1902, no record was kept of the ages of the persons attacked. For the period September 1, 1902, to September 1, 1903, the number of cases occurring in the various periods of life was as follows:

AGE BY YEARS.	NUMBER OF CASES.	NUMBER OF DEATHS.	CASE MORTALITY.
Less than 1 year	0	0	0
1–5	1	1	100.0
6–10	6	4	66.6
11–15	13	10	76.9
16–20	32	22	68.7
21–25	24	18	75.0
26–30	37	34	91.8
31–35	18	16	86.6
36–40	24	20	83.3
41–45	17	16	94.1
46–50	8	7	87.5
51–55	7	7	100.0
56–60	6	6	100.0
61–65	3	3	100.0
65 and over	1	1	100.0
Unknown	1	1	100.0

So far as the above statistics go to show, plague would seem to be a disease of early and middle adult life. These figures can scarcely be accepted, however, as representing the true facts in the case, as the disease so especially affects the Chinese portion of the Manila population, which largely consists of able-bodied men of the working age, and includes but few Chinese children and old persons, as the latter usually prefer to return to China to spend their last years of life, and relatively few births occur among the persons of this nationality.

Proper understanding of the relation of age to the occurrence of the disease should, therefore, be limited, in the case of Manila, to figures based upon the Filipinos class, the data in respect to which are not as yet sufficiently comprehensive to warrant the basing of any conclusions thereon. From the above figures it would appear that the chances of recovery from plague are best in early adult life.

Plague is a disease which, in Manila, is almost exactly six times as liable to occur in males as in females. Thus out of a total of 970 cases, 829 occurred in males and 141 in females, while for the past twelve months there have been 160 cases in males and 38 in females. This is to be explained by the fact that the disease is largely confined to the Chinese population, which is almost wholly composed of adult males; there being, according to recent estimates, but some three hundred Chinese women in the city. On the other hand, relatively more cases occur among women than men among the Filipinos, which is explainable by the fact that the coolies of the lower class Chinese largely intermarry with Filipino women, who are thus brought into relation with a class peculiarly susceptible to the disease, and are placed under conditions as to habitations and surroundings whereby they become much more exposed to the danger of contracting the plague infection than are their sisters living under more sanitary surroundings. Another factor operating for the occurrence of a greater number of cases in men than women is that the lower class Chinese men usually go barefooted, so that plague infection through accidental lesions of the skin is much more liable to occur than among women, even the poorest of whom ordinarily wears some protection for the feet in the form of the loose slipper of the country.

During the entire period of the existence of plague, of the total number of 970 cases occurring 577 were alive and 393 were dead when found. For the twelve months period, September 1, 1902, to September 1, 1903, out of 198 cases, 107 were alive when reported and 91 were dead. This condition depended upon several factors. The most important of these is due to the common failure on the part of persons of the less educated classes in Manila to call in medical attendance in case of sickness of any character. This is due to ignorance and fatalistic ideas, to dislike of modern medical methods and drugs on the part of both Chinese and Filipinos, and because until recently there was no educated physician in the city who could speak to the Chinese in their own tongue and thus secure their confidence. In probably not a few cases, especially among the Chinese, the nature of the disease was not recognized before death. Where it was understood, its existence during life was wilfully concealed in many instances for the purpose of avoiding the annoyances and interference with business incident to disinfection and quarantine—but such concealment could not be continued after death, since burial could not be had without a permit. Finally, plague is often acute in type, particularly the pneumonic form, and the stricken persons may succumb very rapidly to its influence. The fact that such a large proportion of the cases developing were not found during life has materially hampered the sanitary authorities in the work of stamping out local infections at as early a stage as possible. Lack of coöperation and passive opposition of this sort is a serious obstacle to the attainment of good sanitary results, but obstruction of this sort is naturally so difficult of legal proof as to render it practically impossible to secure the conviction of the offenders before the courts.

The only case of plague infection known to have occurred in those looking after plague cases, developed in a Filipino morgue attendant at San Lazaro Hospital during August, 1903. This man had slightly burned himself with carbolic acid on the outside of his wrist, leaving a raw surface at the time the infection presumably took place. On August 17 it was part of his duty to sew up several bodies dead of plague, upon which autopsies had been performed, and it is easy to understand how during this task a sore located on the outer aspect of the wrist might readily have been bathed in plague secretions and thus become infected. The attendant was warned to protect his sore, but it would appear that he did not do so. On August 19 he developed a high temperature, followed by characteristic symptoms of plague, from which disease he died on August 24. An interesting feature of plague in the Philippines would seem to be the apparent disinclination of the disease to spread directly from sick to healthy persons. Infection seems rarely to have occurred in this way, but to have generally proceeded from some outside source, from which, however, several individuals might have become infected at about the same time. Of 374 plague contacts quarantined at the Detention Camp between January 1 and May 19, 1903, but nine developed plague, and of those but three developed the disease after the fourth day of isolation. With such a small percentage of contacts showing the disease it was thought that their quarantine might safely be abandoned, and this conclusion was also reached elsewhere during the outbreaks in Australia and in Honolulu. So far, there has been no apparent reason to regret having taken such action in Manila.

Plague contacts were at the outset scrupulously quarantined at the Detention Camp for a period of nine days. During the absence in quarantine of the proprietor, his residence or store was necessarily closed, or if opened for disinfection and repairs this was frequently done under circumstances permitting of theft by the dishonest. Any business affected was closed. As a result there was much complaint by the Chinese and a tendency to evade the sanitary regulations relative to plague in order to avoid the great discomfort and financial loss attaching to the finding of a case of this disease. The Board of Health therefore adopted and put into operation the following procedure:

As soon as a plague case has been located a special police is at once placed over the house and no one allowed to pass in or out. All contacts are removed to San Lazaro Hospital, where they are inoculated with antiplague serum, bathed, and their persons and clothing disinfected, after which they are released. In the meantime the patient has been removed to the plague hospital and the house has been gone over thoroughly by the ratcatchers of the sanitary district, and every effort made to exterminate these rodents. After the ratcatchers have finished, the house and its contents are disinfected and the contacts are allowed to return. Sanitary orders are then served for the repairs to be made on the house, which include making it rat-proof in addition to a general sanitary overhauling. Where houses are in too bad a condition to justify repairs, they are closed, condemned, and destroyed. If contacts are allowed to return to the house they may at once resume their business or calling, but are kept under special sanitary oversight during the period of the incubation of plague. By the above plan, the interests of the contacts are interfered with as little as possible and there is little opposition to the antiplague measures taken.

During the past year there were twenty-three

houses infected with plague, which were declared nuisances by the Board of Health and were destroyed by fire after appraisal as to value. These houses were nearly all old and of little value, and were usually insanitary and in such locations that their destruction for any reason would have been a public benefit. This work of destruction was brought to an abrupt conclusion by the Trozo fire, which rendered so many people homeless that it was thought inadvisable to burn down shelters which, with the onset of the rains, would be urgently needed for the population of an already crowded city. During the past few months, therefore, reliance has been had upon the most careful efforts for the disinfection and repair of such buildings, which were again thrown open for temporary occupancy.

It is proposed now to prepare a list of all houses in the city in which plague cases have occurred, or plague rats have been found, during the past four years. These houses are then to be carefully inspected, and any repairs necessary to place them in the best sanitary condition will be ordered, and completion of the work required before the end of the present calendar year, when a cyclic increase of plague under the more favorable meteorological conditions of the dry season might otherwise be expected to occur.

Much has been done in the prevention of plague through the destruction of rats, as there is no question but that these rodents are potent agents in its spread. In fact, so susceptible are they to the disease that perhaps plague should be regarded, like glanders, as primarily a disease of the lower animals, but capable also, under proper circumstances, of transmission to man. During the year 1902, with the great diminution of plague cases and with the energies of the health department concentrated against cholera, the catching of rats, carried on so successfully during the previous year, was discontinued. In February of the present year the recudescence of plague necessitated the organization of a corps of ratcatchers, of whom six were assigned to each sanitary station. In April additional ratcatchers were authorized for the specially infected districts, and a public bounty was offered for rats delivered at any sanitary station. As a result, there have been 75,639 rats destroyed by the health department in the space of six months. The greater number of these rats were captured in the districts worst infected with plague. In addition to the ordinary destruction of rats by householders, some 500 traps were loaned to the Chinese Chamber of Commerce, for use by the Chinese. The sanitary department was, and still is, unable to secure for its purposes a sufficient number of traps, 3,000 of which were ordered some months ago. Of the 2,500 traps on hand, too large a proportion are of the large wire variety, which, experience has shown, rats are relatively disinclined to enter.

In addition to the use of traps, poisoning has been freely practised, but without apparently obtaining results to compensate for the labor involved. Various sorts of poison and all kinds of baits and combinations have been tried, but without satisfactory results. While elsewhere the use of poison has been very successful in rat destruction, here the number so destroyed has been disappointingly small. Relatively few poisoned baits seem to be disturbed and only a small number of rats so killed are found.

A very successful means of destruction is by the ratcatchers exploring likely-looking retreats with their hands or sticks, or in the rainy season by pouring water into their underground burrows. Many of the ratcatchers catch the escaping rats with their bare hands, without regard for the bites which are sure to be received. An effort has been made to secure ferrets for this work, but so far without success. At one or two stations portable furnaces for driving rats out of their burrows by sulphur fumes have been tried. Out of a total of 75,639 rats captured, 35,191 were caught in traps, 36,956 by ratcatchers with their hands and sticks, 3,072 by poison, and 420 were purchased.

As illustrating the effectiveness of the work of the ratcatchers, it may be mentioned that plague was discovered in a rat caught in a large building on Calle Santa Elena on February 9. The ratcatchers of the district were at once sent there and caught seventy rats in one day, and about two hundred were taken from the building and its immediate surroundings during the month.

Rats captured are tagged with the street and number of the house in which caught, and where not decomposed are sent to the laboratory for examination. It is of course impossible, with a limited number of observers and the pressure of other work, that the total number of rats caught should be examined post mortem, and the changes incident to the recent moving of the biological laboratory has also interrupted the work. Out of the total number of rats examined up to September 1, 1.69 per cent. were found to have plague. The relative proportion of affected rats decreased as the disease subsided among human beings, 2.47 per cent. being so affected in the month of February and none during the month of June and subsequently.

The proportion of affected rats captured is not, however, a fair index of the actual prevalence of the disease among the rat population. The plague rat is a sick rat, which naturally seeks seclusion, and is not impelled through a vigorous appetite to destruction by trap or poisoned bait. Only those in the early stages of the disease are thus liable to capture by ordinary measures, and rat destruction would seem to be of value not so much through the destruction of existing infection as through the removal of susceptible, but as yet unaffected material by means of which the disease may subsequently be spread. In the present epidemic in Hongkong, certain observers claim to have found plague bacilli in a large variety of domestic animals and fowls, and the tendency there has been to regard rats as only one of many agents in the spread of the disease. As far as the epidemic goes in Manila, however, there would seem to be little evidence to corroborate this belief.

By far the most effective measure of prevention against plague has been found in Manila in prophylactic inoculation of the classes especially susceptible to the disease. This was carried out in 1901 with good results, some 25,000 inoculations being made. Its effect has, however, been particularly noticeable during the present year, when it has been possible to compare the movement of plague in the Chinese, who were largely subjected to inoculation with that in the Filipino population in which no prophylactic inoculations were performed. The occurrence of plague in these two classes has been as follows:

MONTH.	CASES IN FILIPINOS.	CASES IN CHINESE.	TOTAL CASES.
January, 1903	2	0	2
February, "	10	7	17
March, "	16	25	41
April, "	15	35	52*
May, "	10	16	26†
June, "	23	9	32
July, "	12	2	14
August, "	10	1	11
Total	98	95	198

*Two cases in Americans.
†Two cases in foreigners.

Near the end of April, inoculation of the Chinese against plague was begun by the municipal physician for the Chinese, and on May 11 the general inoculation of this class of the population was ordered and carried out at the various stations of the Board of Health. Up to the month of June, 60.4 per cent. of all the plague cases occurring in the city of Manila were furnished by 21,230 Chinese, while 189,782 Filipinos, a population about nine times greater, furnished but 39.6 per cent. of cases. As the number of inoculated Chinese increased, a marked diminution of plague cases among them was noted. For the month of June, the Chinese furnished but 28.1 per cent. of the total cases; for July but 14.4 per cent., and for August but 9 per cent., the Filipinos supplying all the other cases. On June 30 there had been performed 11,135 primary and 3,608 secondary prophylactic inoculations, which meant that slightly over half the Chinese population had been partially immunized, and about one-sixth completely protected against plague. As the inoculations were, however, carried out largely in the most infected districts of the city, and as the Chinese living in the most insanitary houses of these districts were largely those subjected to the operation, the very great reduction of the Chinese plague rate, as compared with the total number of this class partially immunized, can better be understood. The result of this general inoculation of Chinese were not only striking as respects their racial class, but were particularly well shown in individual instances within that class. Thus it has happened in a number of instances that the only uninoculated individual in a Chinese lodging-house has acquired the disease while his associates, living under identically the the same conditions, but who had been inoculated a week or ten days previously, have entirely escaped. Complete protection can only be assured by secondary inoculation, though apparently a primary inoculation alone is not without a certain advantage in this respect. Several instances have occurred, however, in which persons receiving only the primary inoculation have contracted the disease subsequently, but in no case has it happened that the disease has appeared in an individual who had received a secondary prophylactic inoculation. So obvious has been the success of the process to the Chinese themselves, that while at first many were disinclined to undergo the procedure, within a month the general feeling had entirely changed in its favor. Inoculation as practised here has been accompanied by absolutely no untoward results, nor has the local reaction ever been sufficiently severe to cause undue discomfort or as much inconvenience as would be due to vaccination. The weak point of the method consists in the requirement for a secondary inoculation after a lapse of ten days. The necessity for this is difficult to be understood by the coolie, and it is not as easy to secure him for the second operation as it was for the first inoculation.

Besides measures against plague taken on land, efforts have been made to prevent the transfer of the infection into or out of the city of Manila. Vessels running between Manila and Chinese and other infected ports have been frequently fumigated with sulphur by the Quarantine officials to prevent the possible introduction of plague-infected rats, while the inter-island boats have been fumigated to prevent the carrying of infected rats from Manila to other points in the Archipelago. Further, Chinese arriving at Manila have been detained until given prophylactic inoculations against plague.

The present condition in Manila with respect to plague should be relatively a cause for congratulation. While the disease certainly acquired a strong foothold in 1900 it has never been able to prevail as generally as in other cities in which it has become established, although conditions here are such as would seem to favor its spread. The degree to which it has prevailed in the city is quite insignificant as compared with the great loss of life which it has produced in China and India. The calendar year 1903 has been one of the greatest plague years known. In Manila the total number of cases has fallen under two hundred during the period of eight months, while in Hongkong there were 1,399 cases up to August 22. In India the ravages of plague so far this year have been frightful, and the official reports from Bombay state that in that city, with its total of 770,000 inhabitants, there have occurred, during the six months from January 1 to June 30, more than 19,800 deaths from this cause. Had plague prevailed in Manila to the same extent as in Bombay, there would have been more than 5,000 deaths from this disease during the first six months of the present year. Compared with that for many other cities in the tropical Orient, the experience of Manila may justly be regarded as fortunate and fairly to be attributed to the effectiveness of the preventive measures employed. If it has not been possible to stamp it out as yet, at least the disease has been held down within reasonable bounds. There is reason to hope that a continuation of the present sanitary policy will bring steady improvement and may ultimately result in the extermination of the plague infection from the islands.

REPORT OF A CASE OF BRAIN TUMOR INVOLVING THE RIGHT LATERAL VENTRICLE.*

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK.

CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL AND THE HARLEM HOSPITAL; ATTENDING NEUROLOGIST TO THE LEBANON HOSPITAL.

C. P., born in the United States; nineteen years of age; single; stenographer and typewritist by occupation; was admitted to the Manhattan Eye and Ear Hospital January 12, 1903, where she was first seen by me in consultation with Dr. Herman Jarecky. At that time she was totally blind, as the result of an intense bilateral papillitis, the elevation of the nerve-head in each eye equalling from six to seven dioptres.

The eyeballs were slightly prominent, and both pupils were dilated and rigid. The following history was obtained from the patient and her family: During childhood she had measles, but no other infectious disease. She also had occasional earache without any discharge from either ear. In girlhood she was subject to frequent attacks of headache, chiefly occipital, but not very severe. Menstruation began at her seventeenth year, was always irregular in periodicity, and from four to five days in duration. The last menstruation took place four months ago. She has never indulged in alcoholics, but has used tea excessively. She has never met with an injury of the head. Family history unimportant.

About nine months ago she began to suffer from unusually severe attacks of headache over the right frontal and occipital regions, occasionally occurring in the day-time, but generally at night, awaking her from sound sleep and lasting from two to three hours. The headache occurred with regularity every night for several months. The more severe paroxysms were accompanied by

*Read before the New York Neurological Society, December 1, 1903.

vomiting. She also experienced sudden attacks of vertigo which often caused her to stagger. These attacks have persisted. While typewriting she recently noticed a lack of dexterity of the left hand, affecting chiefly the little and ring fingers, which were used only with extreme effort. Two months ago she suddenly discovered that she was blind in the right eye, and that the vision of the left eye was slightly dimmed. One month later the left eye became similarly affected. Since then she has been totally blind.

She remained in the hospital about two months. During this time she frequently complained of severe headache, particularly in the right temporal and parietal regions, often associated with vomiting, vertigo, and mild delirium, and, later, with attacks of tonic left facial spasm. Involuntary urination also occurred from time to time. In addition to the ocular trouble for which she was admitted, there was very slight left hemiparesis, including the lower branches of the facial distribution, and astereognosis affecting the left hand without disturbance of general sensibility, but associated with diminution of muscular sense and sense of position. The left knee-jerk was more pronounced than the right, but ankle-clonus was absent. The urine was analyzed repeatedly and found normal, and the results of further physical examination proved negative. The pulse ranged from 62 to 100; average, 78. In addition to general management, the treatment consisted of thorough mercurial inunction, followed by increasing doses of iodide of potassium.

As the vision and ocular condition had not improved, she was discharged.

During her stay in the hospital, I examined her several times, and made the diagnosis of cerebral tumor involving the right hemisphere, but was undecided as to its exact location.

She then entered my neurological service at the Lebanon Hospital (March 7, 1903), and remained nearly three months. Exploratory operation was advised, but the family refused consent. She was in bed the greater part of the time, as she could neither stand nor attempt to walk without producing vertigo. Occasionally, she was allowed to recline in a chair. She frequently complained of severe general headache, more on the right side, often accompanied by vertigo and tonic-clonic spasm of the left side of the face. She vomited occasionally and was often delirious at night. At times involuntary discharge of urine and fæces occurred without loss of consciousness. Her mind was generally clear. She was very patient and hopeful, and always spoke intelligently, her greatest anxiety being in regard to the possibility of permanent blindness.

The following is the record of the physical examination made in the latter part of March: Slight prominence of both eyeballs; pupils equally dilated and rigid; no perception of light; bilateral papillitis, elevation of nerve five to six dioptres; complete obscuration of the outline of the disk in both eyes; some œdema of the retina, but no retinal hemorrhages; left facial paralysis affecting only the lower branches; no disturbance of sensibility in the trigeminal distribution; tongue protruded well without deviation; slight tenderness on pressure over both supraorbital foraminæ; no increase of pain on percussion of cranium; sense of smell normal; chronic catarrhal otitis media with slight impairment of hearing on both sides. The *left upper extremity* is slightly paretic, as manifested by some weakness in resistance to passive movements; no muscular rigidity; voluntary power preserved; general hypæsthesia of the entire extremity, the tactile, pain, and temperature senses being but slightly diminished as compared with the opposite side; complete loss of muscular sense, and the sense of position and location in the hand and fingers, and some ataxia; the "spacing sense" over the hand and wrist is abolished, two points of the æsthesiometer are not distinguished when two inches apart; *astereognosis* is absolute in the left hand; she is unable to recognize by touch any familiar object. (The stereognostic sense in the right hand is perfect.) In the *left lower extremity* there is slightly diminished resistance in the posterior thigh muscles; the knee-jerk, and Achilles reflex are moderately increased; no ankle-clonus; plantar reflex feeble and of the Babinski type; muscular sense and sense of position in the foot and toes slightly diminished; general hypæsthesia affecting all forms of sensibility; astereognosis in the foot is not demonstrable. The right upper and lower extremities are normal. Further examination, including the internal organs and the analysis of the urine, resulted negatively. The convulsive attacks varied in character and gradually increased in frequency. At first there was tonic left facial spasm only. Then, in addition, this was followed by clonic movements of the face and nystagmus, and, later, rigidity of the post-cervical muscles and retraction of the head occurred, all without loss of consciousness. In the early part of May the headache was often accompanied by delirium or more or less hebetude. On the 18th she complained of sudden vertigo, which was at once associated with tonic and clonic spasm of the left face, arm, and leg, followed by left hemiplegia and rotary nystagmus, which lasted several minutes without loss of consciousness. Four similar attacks occurred the same day, the last being accompanied by involuntary urination. On the 22d, after severe headache and vomiting, she had an attack of generalized tonic convulsion (more marked on the left side) with conjugate deviation of the head and eyes toward the right side, lasting several minutes, in which she was unconscious for the first time. Toward the end of May her condition had become much worse. There was fulness of the veins over the forehead, indicating venous stasis, and horizontal nystagmus, more in the right eye. The left external rectus muscle was paralyzed. The blindness and the condition of the eyegrounds were unchanged. In addition to the pronounced facial paralysis, which was previously limited to the lower branches of the nerve, the orbicularis palpebrarum was decidedly paretic. There was increased faradic irritability in the facial nerve and muscles. The left knee-jerk was exaggerated and accompanied by ankle-clonus. Both great toes were maintained in dorsal flexion, and the Babinski reflex was exquisitely demonstrable on both sides. The muscular power in all extremities was intact as at previous examinations. During her stay in the hospital the pulse ranged from 80 to 100; temperature 98° to 99°; respirations, 24. After consultation with Dr. Jarecky and the patient's family consent for operation was at last obtained.

On May 30, 1903, she was admitted to the Presbyterian Hospital and placed under the care of Dr. A. J. McCosh for exploratory operation.

She continued in about the same condition. On June 6, while conversing with me, she suddenly became unconscious. There was pronounced tonic spasm of the extensors of all four extremities and both sides of the face (more marked on the left side), all limbs being rigidly extended; conjugate deviation of the head and eyes toward the right side with re-

traction of the head; teeth firmly clenched and slight frothing from the mouth (the tongue was not, bitten). Both eyes closed; pupils unchanged, face pale; pulse regular. There were no clonic movements. The attack lasted about three minutes and terminated in complete muscular relaxation, slight horizontal nystagmus, and rapid and almost abrupt return to consciousness. She said, "I feel tired, sleepy, and slightly dizzy." She was unaware of the attack, but, in reply to my question, she said the left arm felt weaker than it did an hour before my visit. The rigidity quickly returned in the left arm and leg, but in a milder degree, and was still present forty minutes later, when she was lapsing into sleep.

On June 9 she was examined in consultation by Dr. M. Allen Starr, who concurred in the diagnosis, and thought there might be multiple lesions to account for the symptoms. He agreed as to the advisability of immediate exploratory operation.

Two radiographic pictures were made by Dr. Henry P. Mosely, director of the *X*-ray Department of the hospital. One exposure was made through the occipital region and the other laterally.

The attacks of general tonic convulsions, as above described, became more frequent, the headache and vomiting more severe, and she was rapidly losing ground.

The following is the report of Dr. McCosh: "Operation June 11, 1903, at ten P.M. Chloroform anæsthesia. A bony flap 3½ by 2½ inches with the hinge at its lower portion was raised from over the area on each side of the fissure of Rolando. The bone was divided by means of electrical burrs and saw. When the flap was lowered it was at once seen that the intracranial pressure was markedly increased. On opening the dura, the brain, slightly congested on its surface, bulged outward very prominently. There was an indistinct sense of fluctuation but no indications of tumor formation. A hollow needle, attached to an aspirating syringe, was inserted toward the right lateral ventricle. At the depth of 1½ inches, it withdrew about two and a half ounces of clear straw-colored fluid. (Analysis in Laboratory. "Alkaline; sp. gr., 1010; albumin, trace, less than 0.05 per cent.; nucleoalbumin, trace; chlorides, 0.3 per cent.; reduces Fehling's solution; no cellular elements.") (F. W. Hastings.)

The point of the needle was evidently in a large cavity, and as the pulse showed some signs of weakness, it was thought best not to withdraw more fluid. Through the needle there was then inserted a single strand of silkworm gut for drainage. On withdrawal of the fluid, the brain was seen to collapse within its normal boundaries. The dura was sutured after withdrawal of the needle, and the bony flap replaced and sutured.

The shock of the operation was comparatively slight. The drainage of the clear fluid from the skull was very free. It was estimated that up to the time of her death, from one to two pints escaped daily alongside, apparently, of the silkworm gut strand which was not disturbed. The intracranial tension was so great as to force the bony flap upward, where it remained, thus causing a permanent projection of the scalp in the form of a cone with an elevation of several inches.

On return to consciousness after the operation, she was found to have complete left hemiplegia with rigidity. In a few days the rigidity disappeared, leaving the arm and leg in a condition of permanent flaccid paralysis. The intracranial pressure being relieved, there was complete cessation of the severe headache, vomiting and convulsive attacks. At times there seemed to be some improvement in vision, for she claimed to see shadows, and also correctly described the style of dress worn by the nurse. Loss of rectal and vesical control persisted. She was often delirious and talked noisily, but this may have been partly due to the frequent administration of morphine. The astereognosis and other sensory symptoms were unchanged. She died July 8 from lobar pneumonia, four weeks after the operation, and seventeen months after the onset of the symptoms of brain disease.

The autopsy was made fifteen hours after death by Dr. George A. Tuttle, pathologist to the hospital, who has kindly furnished the following report: "The examination was limited to the cranium and its contents. The bone-flap was found forced outward against the scalp and there was oozing through two or three openings along the scar. On removing the calvarium, a ragged opening was made in the surface of the brain where the flap of bone was adherent. The brain tissue in the region of the operation was quite soft. Gently separating the ragged tissue, the right lateral ventricle was exposed, and a soft red mass presented beneath the parietal portion of the surface. The growth was red on its surface and very soft. Several fragments were removed for microscopical examination. The cut surface was mottled gray and pink, not so red as the outer surface. The tumor was about the size of an egg. It was extremely soft and friable, and appeared to spring from the inner wall of the ventricle. Whether it originated in the choroid plexus, I do not know. The microscopical appearance seemed to be rather against such an origin. I should class the tumor among the sarcomata, probably a glioma, though we were unable to demonstrate the glioma cells. The brain was placed in formalin solution and examined a few days later. The decomposition which had begun continued in the preserving fluid, so that most of the hemisphere, including the tumor, was very much softened. On opening the ventricle two organized blood-clots were found, and the tumor mass had become almost completely liquefied. The surface of the ventricle was smooth and the cavity considerably dilated. The origin of the growth could not be determined. There were no indications of tumor formation in the superior parietal lobule or Rolandic area. Macroscopically, all other portions of the brain and meninges appeared perfectly normal."

No further histological examination was made on account of the disorganized condition of the brain tissues. Of course, gliomatous invasion of the parietal and Rolandic cortex may have been present, although there were no macroscopical indications of such condition either at the time of the operation or at the autopsy. The tumor mass which was confined to the cavity of the right lateral ventricle suffices to explain all of the clinical manifestations of intense intracranial pressure (headache, vomiting, vertigo, delirium, papillitis, etc.). In the absence of a microscopical study of the cortex, the cause of the astereognosis and the Jacksonian type of convulsive seizures, etc., must remain undetermined, unless we assume that they were due to the upward pressure of the ventricular neoplasm. The paralysis of the sixth nerve may be ascribed to indirect pressure against the base of the skull, for had it been due to destruction of the abducens nucleus a paralytic conjugate deviation of the eyes would have been present. The puncture of the brain at the time of operation, in all probability caused hemor-

rhagic extravasation in the tumor which resulted in permanent hemiplegia.

To summarize: A girl nineteen years of age, without history of traumatism to the cranium or previous infection, is attacked with severe headache. This is soon accompanied by vomiting and vertigo, and in the course of a few months blindness is developed. All of these symptoms continue unabated with the addition of astereognosis of the left hand, slight left hemiparesis with hypæsthesia, and, later, unilateral convulsive attacks limited to the face for several months, subsequently involving the arm and leg, and ultimately becoming general, mostly in the form of tonic muscular spasm; rectal and vesical incontinence, and paralysis of the left abducens. Up to the time of operation, the voluntary power in the left upper and lower extremities was preserved, although there was some perceptible weakness on resistance to passive movements.

At the first examination there was no doubt as to the existence of a brain tumor involving the right hemisphere. The presence of complete astereognosis without interference with general sensibility, and the absence of paralysis led me to assume that the lesion was located in the right superior parietal lobule, as in the classical case reported by Dr. Charles K. Mills of Philadelphia about three years ago. But the evidence of such intense intracranial pressure as manifested by the headache, vomiting, delirium, pronounced papillitis and blindness, seemed to militate against the diagnosis of such a circumscribed lesion. The subsequent development of facial spasm, which was for a long time limited to the left side of the face, later the left arm becoming similarly involved, and ultimately the left leg, the attacks of unilateral convulsion without loss of consciousness being followed by transient hemiplegia, presented a characteristic picture of irritative disease affecting the right Rolandic area, originating in the facial center. On account of the predominantly tonic character of the spasm, the lesion was thought to be subcortical.

When I examined the *x*-ray picture, I was unwilling to interpret it as indicating the presence of a tumor involving so large an area as outlined on the plate, as the existence of such an extensive growth was entirely at variance with the clinical phenomena. In the light of the post-mortem findings, however, the tumor occupying the ventricle (being of greater density than the surrounding structures) was approximately correctly delineated on the plate. The skull was opened not only for the purpose of exploring the right superior parietal lobule and the Rolandic area, and removing any discoverable and accessible neoplasm, but also for the permanent relief of the excessive intracranial pressure. Although the tumor was not found at the time of operation, and was thought to be inaccessible, yet the continuous and abundant escape of cerebrospinal fluid, and the large opening in the skull resulted in the complete cessation of all irritative symptoms. It is worthy of note that the tumor in its further growth after the operation naturally sought the lines of the least resistance, so that at the autopsy it was found almost exposed through an opening in the cortex. Had the operation been performed several months earlier, is it not probable (in the light of post-operative developments and the post-mortem revelation) that a second surgical exploration may have exposed the exact location of the tumor and its accessibility to successful removal?

I have been unable to find an analogous case of tumor of the lateral ventricle reported in neurological literature.

CONTRIBUTIONS TO THE OBERSTEINER-REDLICH THEORY OF TABES DORSALIS.

By G. B. HASSIN, M.D.,
CHICAGO.

In the present article I shall mention briefly new data which may help to the understanding of the true nature of tabes dorsalis. In my recently published paper on "Pathogenesis of Locomotor Ataxia" (*Clinical Review*, July, August, and September, 1903), these data could not find place for many reasons. The chief one is that I became acquainted with the facts I am going to discuss comparatively late, when my first article was almost ready for printing; and secondly, these new data are so important for Obersteiner's teaching, that I preferred not to increase the volume of my paper and to devote to them a separate article.

I discussed, in my first paper, the most important theories of pathogenesis of tabes dorsalis and had to come to the conclusion that the most satisfactory tabes theory is that of Obersteiner-Redlich, namely, that from the spinal roots some pathological process extends to the pia mater (chronic inflammation, tumor, etc.), compressing the posterior roots and thus producing their degeneration with the subsequent atrophy of the posterior columns. I referred to the facts in favor of this theory, and will not repeat them, but will point out that lately, especially in France, there has arisen a movement among the most competent and famous neurologists in favor of the membrane theory of tabes dorsalis.

The characteristic feature of this movement is the attempt to establish a connection between the pathological processes in the spinal cord and those in the membranes.

In this regard I must refer to the investigations of Marie-Guillain. The former, as it is known, promulgated the old and forgotten theory of Marius Carré on the affection of the spinal ganglia as the essence of tabes; but as one can see now from his latest paper, he has given up entirely his former theory, and says: "The affection of the spinal ganglia in tabes is too insignificant and can in no way explain the changes observed in the spinal cord." Further, Pierre Marie puts three noteworthy questions: (1) Why does a posterior meningitis exist in tabes dorsalis? (2) Why, the lesions of the meninges being of a diffuse character, are they limited only to the posterior columns? (3) How, in short, can one explain the pathogenesis of tabes dorsalis.[1] In my article[2] I endeavored to establish that a *primary* posterior meningitis does exist in tabes dorsalis, which meningitis, in the opinion of some authors, is observed in not all cases of tabes, especially fresh ones (Leyden), and by some authors (Strümpell) is held as a secondary process. The first question of Marie shows that he accepts the fact that tabes dorsalis is always associated with a meningitis; but why it is so, why this posterior meningitis exists, is a question which I did not touch upon, because all I held necessary to establish was the fact that in tabes dorsalis meningitis posterior is of a constant appearance and that this lesion is a primary one. The assertion of such a competent neurologist as Marie that meningitis always accompanies tabes is very important for the membrane theory of tabes, although the connection between the changed spinal membranes and the affection of the posterior roots Marie understands and explains in a different way.

According to the membrane theory of Obersteiner-Redlich, the thickened spinal membrane compresses the posterior roots, especially at the place of their entrance through the pia mater, where they are deprived of myeline, and present, therefore

a *locus minoris resistentiæ*. Here one can see strangulation of the posterior roots which is not an artefact, as Nageotte thinks, but is pathological, as every one can convince himself by the study of preparations properly made. The compressed posterior root fibers become degenerated and atrophied, producing thus sclerosis of the posterior columns. Marie, however, explains it differently. He asserts that the posterior spinal columns and posterior roots possess their own peculiar lymphatic system; a similar lymphatic system exists also in the pia mater. This was proven long ago by investigations of Guillain,[3] Abundo, Leon Lépine, and others. The posterior columns, posterior roots, and pia mater form a whole regarding the development of the lymphatic system, and the affection of this whole is the essence of tabes dorsalis. According to Marie-Guillain, we must admit that in tabes this lymphatic system becomes affected primarily because of syphilis, and therefore we meet in tabes the simultaneous affection of the pia mater, posterior roots and posterior columns.

Such is the new theory of pathology of tabes given by Prof. P. Marie. Its similarity with Obersteiner's teaching is that both accept the important rôle lesions of the spinal membranes play in the production of tabes, and in this fact I see the progress of the membrane theory. In my opinion Marie only develops further Obersteiner's teaching, when he attempts to explain why only the posterior parts of the spinal membranes are affected. Whether or not this affection depends upon the peculiar lymphatic system of the spinal membranes or on the peculiar distribution of the blood-vessels is another question; it is only important to establish the fact that in discussing the question of the pathology of tabes the greatest attention must be paid to the condition of the pia mater.

Still greater similarity with Obersteiner's theory we find in that of Nageotte, who in the years 1894 to 1903 published a series of papers[4] on the basis of pathologico-anatomical investigations made first in the laboratory of Raymond and later in that of Babinski. He came to the conclusion that tabes dorsalis is the result of a peculiar form of root-neuritis ("névrite radiculaire interstitielle transverse"), the result of affection of that part of posterior roots which is located between the spinal membranes and the spinal ganglia. The neuritis is of a syphilitic origin, and the sequel of a syphilitic meningitis. The latter affects the roots by a process which "rules the anatomical course of the lymphatic vessels." The meningitis is a constant appearance in tabes dorsalis, but not its essence; meningitis produces tabes through the posterior roots, which thus become affected secondarily to the spinal meninges and then undergo degeneration with the subsequent atrophy. The degeneration is not of a Wallerian type, but has the character of an inflammatory process—axial segmentairy neuritis ("névrite segmentaire axiale"). The degeneration of the spinal fibers begins in the central gray matter of the spinal cord, spreading toward the spinal ganglia.

The similarity of Nageotte's theory to that of Obersteiner is very great; both admit that the origin of tabes dorsalis must be looked for outside of the spinal cord, namely in its membranes; but Obersteiner holds the affection of the pia mater to be the chief cause of root changes, while Nageotte looks for the source of this affection in the dura mater; also, Nageotte holds tabes to be a sequel of an inflammatory process of the posterior roots ("nerve-root of Nageotte"); Obersteiner holds tabes to be a degenerative process because of compression of the posterior roots by the pia mater. This compression, as Obersteiner has shown, by longitudinal and transverse sections of the posterior roots, cannot be produced by an inflamed and thickened dura mater, *i.e.* by a perineuritic process, and therefore we cannot ascribe to the dura mater the same rôle in producing tabes as that of the pia mater.[5] I shall not stop any longer on a comparison between the two teachings, I only want to say that whatever the difference between Obersteiner's, Nageotte's, and Marie's theories may be, the fact common to all is that the spinal membranes play a great rôle in producing tabes dorsalis; only the manner in which they produce this disease is differently explained by the above-named authors.

The membrane theory receives additional strength in cytoscopical examinations of the cerebrospinal fluid of tabetic patients. In my former[6] paper I only mentioned that cytoscopical examinations, together with cryoscopical examinations, Kernig's sign, and hæmolysis, "are elaborated in relation to different forms of meningitis, not so much for diagnostic purposes as for purely scientific ones; with the latter purpose it is necessary to apply all these methods also in every case of tabes dorsalis, studied clinically. Then it will be possible to obtain some facts for comparison with those obtained from the study of other forms of meningitis, which will make it possible to establish the connection existing between these diseases, or will furnish some new standpoints in favor of the opinion that tabes is nothing but a variety of meningitis." Indeed, if tabes dorsalis is nothing but a variety of meningitis, then the spinal fluid must possess in tabes the same properties as in meningitis. While in a normal condition the spinal fluid does not contain lymphocytes at all, or only a very small number (one or two in the field of the microscope), this fluid in cases of meningitis contains an increased number of lymphocytes. This was shown long ago by investigations in the clinics of Lichtheim and Minkovsky, and we must thus admit that lymphocytosis of the spinal fluid indicates that in a given case we have to deal with an irritation of the mininges, viz., meningitis. If tabes is a form of the latter, we must meet here also with lymphocytosis. The question of lymphocytosis in tabes attracted the attention of the investigators in France, where a large literature has accumulated on this question, and the final result of all investigations (Widal, Sicard, Ravault, Dechy, Joffroy, Dupré, Devaux, Séglas, etc.) is "that lymphocytosis is a law in tabes." It is true that Armant, Delille et Jean Camus did not always find lymphocytosis in tabes (50 per cent. nearly),[7] and that, in their opinion, in no case is lymphocytosis a diagnostic symptom of tabes; but Widal, Sicard, and Ravault have shown[8] that inconstant results of the former authors depend on the false technique they applied, and if one follows the correct technique minutely, lymphocytosis will be always found in tabes.

The investigations of French scientists were confirmed in Germany by Dr. S. Schoenborn,[9] whose paper is almost the only one in Germany regarding the discussed question. Schoenborn examined patients in Erb's clinic in Heidelberg, and always found lymphocytosis in tabes, mostly very well developed.

From the standpoint of the membrane theory of tabes dorsalis, that the latter is a product of meningitis, we must *a priori* expect that every case of tabes will be accompanied by lymphocytosis, and the more recent the case is, the more developed must be the lymphocytosis and *vice versa*, or, in other words, lymphocytosis in recent cases of tabes,

when the inflammation of the membranes is still incomplete, must be one of the most recent and constant signs of this disease. Such a conclusion must necessarily be formed if the membrane theory of tabes is correct. Indeed, Babinski, Nageotte, and Widal found lymphocytosis in those cases of tabes, when the symptoms of the latter were indistinctly developed, *i.e.* in the most recent stages of tabes, and therefore it is no wonder that Widal insists on this as a diagnostic sign of early tabes.

Discussing, in my former paper, the question of the supposed lesions of the olfactory nerve in tabes, I came to the conclusion that "fila olfactoria in passing the (thickened) membranes of the brain will be compressed and at last will become atrophied, first the peripheral part with half of the stratum glomerulosum, and after this the central part," etc.[10] I did not possess at that time exact facts in favor of my opinion, but lately I came across Marchand's paper,[11] who found in one case of tabes complicated with dementia paralytica during life disturbances of the sense of smell; post-mortem examination showed lesion of the glomerula with subsequent formation of glia. This investigation completely confirms our theoretical proposition and gives, together with the facts discussed in the present paper, new proof of the correctness of the membrane theory of tabes dorsalis in the sense of Obersteiner-Redlich. I do not doubt that other propositions mentioned in my first paper will also become confirmed, and at the suitable time I shall publish them.

The Need of Sleep.—Emil Kraepelin says that the most important compensation for all effects of fatigue is sleep. Everybody develops, when awake, a mass of mental effort which cannot be continued long without recurring periods of mental rest. We are capable of the longest mental effort in the forenoon, the evidences of fatigue generally coming on in the afternoon and evening. If no recovery by sleep is enjoyed, the next day will find us with a greatly depressed mental vigor and an increased susceptibility to fatigue. In one case experimented upon, a night's journey in a train with insufficient sleep was followed by a decrease in the rapidity of the mental activity amounting to one-third.

AN ANTISEPTIC TOILET FOR THE HANDS AND VULVA.

By DOUGLAS H. STEWART, M.D.,
NEW YORK.

When my little paper was read before the West End Society it was a most pleasant surprise to find the application of its principles wider than I had thought, and though originally planned solely with regard to the obstetrician's needs, it seemed to be the very thing that general surgeons had long wished for, viz., a method of minimizing septic possibilities without irritating the hands upon which the disinfectant was used. The disappointment which awaits the users of corrosive sublimate has not been relieved by such experiments as the cultivation of anthrax spores after a day's immersion in a one-per-cent. solution of that very poisonous salt. On the contrary, it is fast becoming the general opinion that bichloride is better adapted to the test tube than to the operating room. Green soap and lysol are snares. I have obtained cultures after each and both. Dr. Brodhead, to whom I spoke of this, could hardly credit my remarks, and rightly determined to experiment for himself. He exhibited the following cultures: Ten after scrubbing hands ten minutes with tincture of green soap—seven positives and three negatives. The same followed by a two-minute lysol scrub (1 per cent.), gave six positives and four negatives.

It is scarcely necessary to point out that if such poor results follow the manipulations of one whose care and thoroughness are well known, then the every-day man has little chance of sterility. By way of contrast the doctor took for me twelve tests of his hands (six by one method, six by another), using chlorine, and not one of the dozen was positive.

To obtain a line upon the relative merits of bichloride (1-1000) and chlorine (about 1 per cent.) as hand disinfectants, twenty-five tests were made of each after five minutes' scrubbing in their solutions: Bichloride gave 12 positives, 13 negatives; chlorine gave 1 positive, 24 negatives. The before or check cultures—four for each trial—all took well.

With anthrax and a five-minute immersion, 90 tests: Bichloride gave 56 positives, 34 negatives; chlorine gave 32 positives, 58 negatives. Admitting these results, chlorine is much the surer in action. However, to make certain I made 25 very careful tests of the bichloride. Every single one took. Of the chlorine (25) two took. Then 26 tests were made with the chlorine solution; four were positives and 22 negatives. Of course, when one is using anthrax and immersions of five or ten minutes, the proportion of positives is always large. A very weak solution with time is decidedly more effective than a strong one with a time limit. As for streptococcus, staphylococcus, etc., I have practically never had a culture after the chlorine solution, or if I did, it could be readily attributed to an error of technique. Dr. Brodhead put in the incubating oven test cultures of streptococcus, staphylococcus, and Bacillus coli communis. Some thirty in all, showing what chlorine could do: of all that were exposed to the solution for five minutes—one was a doubtful positive, the rest were negatives. The doctor cleansed the test-loop in a pot of water after each g rm test, so naturally there should have been plenty of floating streptococci, etc. He seemed to think it quite a crucial test that I plunged my badly burned hands into this water and kept them there for some minutes; the right had three open blisters on it, and the left nine. Nothing resembling an infection followed. The bactericidal power of the aceto-chlorine solution is very positive.

I interested Dr. Dawbarn by taking two check cultures and six others of pure anthrax. The six were each immersed in the solution for fifteen minutes, and then all were delivered to the doctor to incubate for himself. The two checks took well, but the six were negatives. He then entered into the study of the solution. This solution presents a remarkable phenomenon, inasmuch as it responds to all the tests for chlorine, and yet little chlorine is given off in vapor form. According to the results of the investigation, the nascent hypochlorous acid is the germicide (plus the nascent oxygen of course). The fluid is in use at the New York Polyclinic Hospital and the City Hospital, and Dr. Dawbarn has had his staff adopt the following technique:

Five minutes' mechanical. Powdered pumice stone, brush, hot water, green soap, and wooden nail-cleaners.

Five minutes' chemical. Two heaping teaspoonfuls of fresh (35 per cent.) calx chlorata and one tablespoonful of U. S. Ph. (36 per cent.) acetic acid to the pint of sterile water. If this solution stands for ten minutes without stirring, the necessary chemical changes are complete.

In sterilizing the vulva a solution one-third the strength of the above should be used. The same for compresses on septic wounds. The temptation is strong to load up this paper with statistics, but I will only say that vulva sterilizations have averaged only one positive in every fifteen attempts, while the test cultures taken before antisepsis have only failed once, and in that instance there were two cultures, one was positive and one negative.

Lately I have been successful in every instance in vulva sterilization, and Dr. Brodhead reports that but five cultures were positive out of seventy-four trials in his tests.

Rubber gloves are just at present in the ascendant. I use them myself; they are a valuable protection to the surgeon.

The technique described seems ample for the average surgeon, but personally I am afraid of soaps and use this:

A teaspoonful of lime and a teaspoonful of powdered pumice on a saucer with wooden nail-cleaners; a basin with two quarts "cool" water mixed with one teaspoonful each of calx chlorata, of table salt, and of aqua ammoniæ, and of carbonate of potassium. In this basin a nail-brush. Dip the hands in this solution, take the wooden nail-cleaners and apply the pumice under and around the nails. If you cannot get them speckless, then dip the wet ends into the chloride on the saucer. Do not get lime on the sensitive skin. Work it under the finger-nails with the stick and the pumice. See that it gets into every possible crevice. Then scrub hands, nails and all, in the solution with the brush. This is the five-minute mechanical that I like best. It is only a preliminary, but it often leaves the hands sterile. A young medical student, Arthur Sherman, who aided me in my research work, took thirty cultures of his hands after this part of the technique. Three were positive. I took twenty-two, with one positive. Several physicians took a number, total 116, and thirteen of these were positive. Of course, a strict bacteriologist would object to all of these tests, because we did not put anthrax on our hands. It was, however, a fair test of hands, as found among medical men, under the conditions of daily life. In every instance there were check cultures, and they took. Sometimes they were molds, but more often mixed cultures.

After thorough washing in the above mixture perform the five-minute chemical as before described.

The surgeon generally prefers an aseptic hand, but in my obstetrical work the antiseptic hand serves me best. Asepsis is very limited in duration, while antisepsis may be maintained indefinitely by dipping the hand and arm into a basin filled with the hypochlorous solution. Should this solution not instantly bleach blue litmus paper, then it should not be employed. Either the chlorinated lime in such case is below standard, or it has been allowed to stand uncovered.

As to comparisons with other techniques: Twenty-eight methods in use or recommended have been tried, and nearly three thousand cultures attempted. Considering the results from every side, the method suggested is far ahead of all others. The only process which might be compared with it is the calcium-sodium carbonate, followed by alcohol and 1-1000 bichloride. This has the following disadvantages: (1) It is irritating; (2) the chlorine seems to be washed away too quickly to be effective. After all, in using any chlorine technique, the question of contact is the vital one.

Finally no one, so far as I know, has been hardy enough to dispute that chlorine will do the work. It is solely a question of availability and perhaps also one of residue, and as the residue here is the acetate of lime, the reader is referred to Cushny and other works on materia medica for data concerning the mild characteristics of the acetates.

It is fitting that I should acknowledge the kindness and courtesy of Dr. S. E. Jelliffe, who put at my disposal every facility of his laboratory.

NOTE.—Since the above was written clinical experience has shown that the solution, as originally recommended, was unnecessarily strong. Should the surgeon's hands have been in contact with anthrax, then full strength is advisable, otherwise use one teaspoonful of acetic acid and two of lime to the pint of sterile water.

121 WEST EIGHTY-EIGHTH STREET.

INSTRUMENTS FOR THE PRODUCTION OF ABORTION SOLD IN THE MARKET PLACES OF PARIS.*

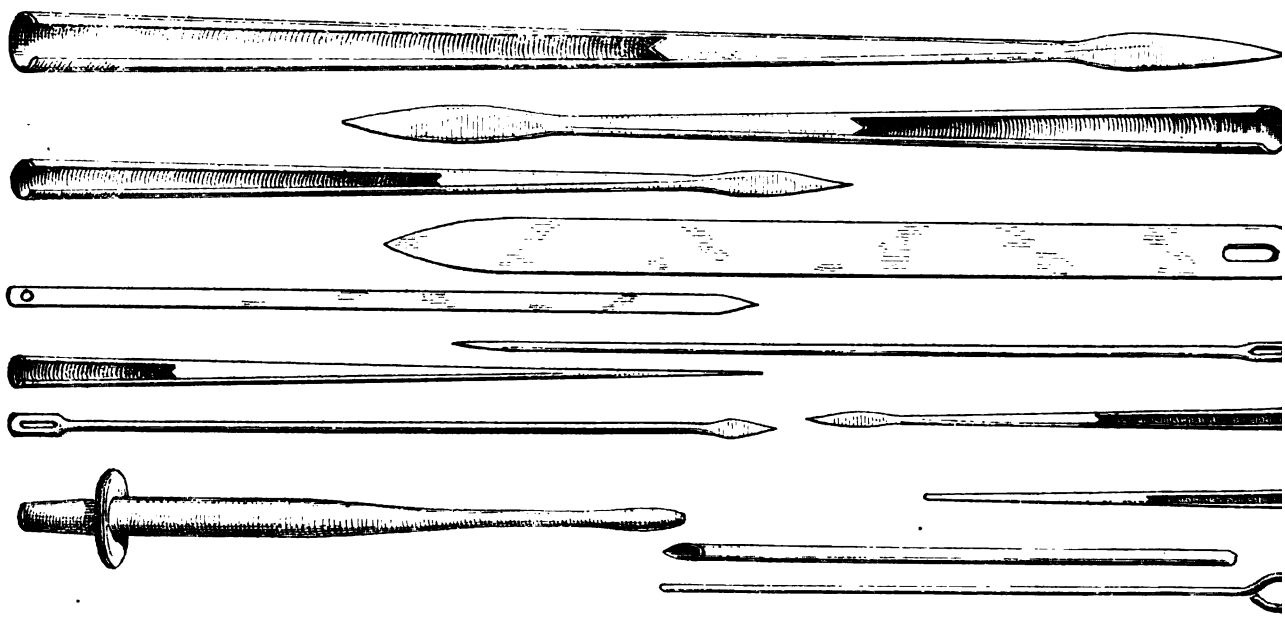
BY FREDERIC GRIFFITH,
NEW YORK.
FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

IN the beginning I will say in defence of myself, that at all times I am on the lookout to learn whatsoever I can from the powers of others. Driven by this desire—or curiosity, if you please to so call it—I have endeavored to meet all comers, and with a result that I have, upon a number of occasions, secured to a varying degree the confidence of individuals whose occupations in life were neither ethical nor legal.

One day in September I strolled through the Boulevard Quinet, interested in the uproar of a transient street market, one of the features of Paris as in many of the cities elsewhere upon the Continent. This market was peculiar in that both buyers and sellers were almost without exception women, and the excitement and turmoil presented beggars description. Passing in and out through the crowds (the aggregate numbers of which may be guessed when I tell of twenty women counted who were far advanced in pregnancy), I at length came upon a shrewd-looking female of thirty-two or thereabouts with a child clinging to her skirts, and who, while seemingly with nothing to sell was most energetically calling in shrill-toned voice what I translated, "For the ladies," "For the ladies." Attracted, I stood to one side, allowing the woman to pass me while seeking an explanation. She eyed me sharply as she came up, but, rightly judging my presence, continued her calls until well past my stand, when she suddenly

*Presented before the Section on Obstetrics and Gynecology of the New York Academy of Medicine.

ceased and began to bargain at one of the booths. Looking about I learned the cause for the interruption in the person of a policeman on duty. When the officer had passed beyond earshot, her cries began anew, and spying a prospective customer in a matron who had paused in the midst of her sundry purchases, flashed before the other's eyes a handful of instruments similar to some in my collection. Accompanying the exposure with rapid explanations as to proper use and praises of the effectiveness of the several varieties. A bargain was soon struck, the purchaser, selecting an instrument to her liking, paid the price asked, namely, ten centimes, equal in our money to two cents, carefully secreted the implement near the bottom of her basket and quickly lost herself to view. A little further along another sale was made. I then addressed the peddler, asking her to show me her stock, as I desired to purchase. She refused at first, but later, crediting my statements, allowed me to choose from her supply, which was cunningly concealed in an inside pocket beneath her apron. Selecting an average-sized and shaped implement, I paid her the usual fee of two sous, which is two cents. Returning by that way upon another market day, I determined to secure a complete collection, and



though I sought patiently I was unable to find her. Later the cause became apparent when a raid upon the many unlicensed peddlers about the place was made by some detectives who came upon the scene from various side streets. It was not until two weeks later that she dared to return. With little persuasion I was then enabled to secure one of each of the several varieties of instruments which she carried, and, though very explicit in explaining the use of them refused absolutely to tell me where she obtained the implements she sold. Viewed mechanically, it will be seen that the various specimens are well made, being of hammered steel save for one exception, filed and well finished, lacking but a nickel plating to compare very favorably with the products of a surgical instrument shop. The general directions given to a purchaser are that the instrument may be used at aty time during the course of gestation. The operator and patient being combined in the same individual, for it is recommended that a woman can best perform the operation unassisted and verily I believe that the average French woman can locate her uterine os as certainly as she can touch the tip of her nose. To facilitate the location of the mouth of the uterus pressure is to be made over the lower abdomen by means of the unoccupied hand. When found the os is to be gradually dilated by a rotary onward motion of the instrument until the sensation of rupture occurs and the escape of bloody fluid proves the success of the first stage of the operation. If not immediately successful, syringing is to be commenced. Hot water intrauterine irrigations quickly complete the operation with little or no apparent after-effects in the majority of instances. When general sepsis occurs the woman is early trundled off to a hospital. The French laity probably understand better than any other people the best method of interrupting pregnancy. The flat, curved instrument I obtained some time later from another of these itinerant vendors, in a portion of the city far removed from the first. This instrument was especially recommended to fulfil any indication. Some of the specimens seem upon a closer inspection, to be not at all unsuitable for the purpose for which they were designed. The spear-head variety partakes of the nature of a dilating forceps as well as being a membrane-puncturing instrument and looks not unlike one of the forms of perforator used by obstetricians. Shown to a number of public women they one and all expressed wonderment at my possessing the instrument, but readily demonstrated to my satisfaction that they thoroughly understood its use. None of the French physicians or surgeons about the several hospitals which I visited and to whom I presented the matter had ever seen the instruments; neither at the Maison St. Lazare or detention hospital for the public women of Paris were they recognized, yet all knew of their existence. Mr Abuthnot Lane of Guy's Hospital in London was extremely interested in the collection, he having spent much time in Paris and in study upon the social questions relating to matters upon this subject. He further expressed the opinion that no English woman would have sense enough to know how to employ the instruments for their set purpose.

The bone irrigator tip was added to the collection as being one of the commonest kinds and sold for one franc, twenty-five centimes, or twenty five cents at all druggists, many hair dressers, milliners stationers, grocers and tobacco shops The irrigation habit is so strongly engrafted upon both male and females in France that a hotel bedroom is considered incomplete without one of the irrigation tubs which look not unlike a baby's bath-tub with bent in sides placed upon short legs upon which the individual sits astride when using it.

40 East Sixty-fourth Street.

SCARLATINAL PANOTITIS; EXFOLIATION OF A PORTION OF THE LABYRINTH; RADICAL OPERATION.*

By CARL KOLLER, M.D.,
NEW YORK.

Elise A., four years old, was taken with the sickness which terminated in total deafness, on May 24, 1903. According to the mother's statement the illness began with vomiting and fever; the vomiting lasted three days. Scarlatina eruption appeared the day after onset, and this was followed two days later by the appearance of a diphtheritic membrane in the throat, with swelling of the glands. In the further progress the diphtheria was a prominent feature. The first evidence of any trouble with the ears appeared at the end of the first week. The child complained of pain and deafness, and this was soon followed by discharge on both sides. Deafness was absolute within twenty-four hours of the appearance of the ear symptoms. When the patient first got out of bed after four weeks' illness, the mother noticed that the child staggered and stumbled frequently, which she attributed to dizziness. This, however, was of short duration. With the exception of a suppurating submaxillary gland on the left side, the further progress toward recovery was uneventful. Up to that time the child had been treated by the family physician and no ear surgeon had been consulted.

At the time of admission to the hospital (July 21), discharge from both ears and considerable swelling of the submaxillary and cervical glands still persisted; the tips of both mastoids were sensitive to pressure. Examination of the ears showed large perforation of the drum on either side, and granulations in the middle ear; on the left side denuded bone could be felt with the probe. Considering the total and absolute deafness, panotitis with necrosis of the labyrinth was diagnosed and an operation decided upon, partly to remove the supposed sequester, partly because it was considered possible that some part of the labyrinth and nerve had escaped complete destruction, and might revive when freed from the surrounding inflammation and suppuration.

Operation.—On July 22 a radical operation was performed on the left side, thoroughly exposing the cavities of the middle ear. The antrum was found to be filled with pus and granulations, and so was the attic; the ossicles were found disconnected from their articulations and imbedded in granulations. From the medial wall of the attic a loose shell-like sequestrum could without difficulty be detached, which upon closer examination proved to be part of the labyrinth, consisting of the superior and external ampullæ, and the adjoining parts of the superior (saggittal) and the external (horizontal) semicircular canals. Another small piece of necrotic bone, loosely connected with the facial nerve and taken from a place below the first piece, resembles most the outer inferior portion of the anulus tympanicus. After it was removed the facial nerve was seen running through the cavity a straight course, outward and downward, being entirely free like the string of a bow; every time it was touched, the face twitched. The bone cavity was smoothed with the electric burr, and tamponaded with iodoform gauze; the opening behind the ear was left open for the present. The patient made an uneventful recovery, and after two weeks the wound behind the ear was closed. Koerner's plastic method was employed to widen the auditory canal sufficiently so that it would adapt itself to the increased caliber of the united middle-ear cavities. These are now entirely smooth and covered with dry epidermis; a newly formed pseudotympanic membrane closes them against the Eustachian tube. But this is the only result of the operation; the hope of a partial restitution of the hearing has not been realized.

*Case presented before the Otological Section of the Academy of Medicine.

Pollitzer defines panotitis as "a disease in which the middle ear and labyrinth become affected by the inflammation either simultaneously or in rapid succession. It occurs chiefly in children, either as a primary affection or in the course of scarlatinal diphtheria, and always affects both ears, leading, after a strikingly short duration, to total deafness. The primary form begins with high fever, which is often accompanied by eclamptic seizures with or without loss of consciousness. The duration of these attacks varies from a few hours to several days. After the return of consciousness, the individual is found to be totally deaf, and a discharge from both ears, with perforation of the tympanic membranes, is usually observed after a few days, but rarely before the return of consciousness. In all cases thus far reported the affection was associated with a staggering, uncertain gait." Pollitzer does not give such a concise picture of the diphtheritic form of panotitis, but he merely says that to it "those cases may be classed in which total deafness arises during the course of scarlatinal diphtheria." He relates, however, a case which in all particulars is a counterpart of this. "In a girl of eight years, on the eighth day of the disease a discharge from both ears was noticed, and on the same day total deafness also ensued. Staggering gait was observed only in the first few weeks after cessation of the diphtheria. Objective examination showed: Right side, perforation of the membrane tympani and polypoid growth in the tympanic cavity; left side, extensive destruction of the membrane. Both sides showed a profuse blennorrhœal discharge. Hearing for all sounds and noises was entirely lost."

Diphtheritic panotitis is the most intense degree of the otitis which seems to be a regular accompaniment of scarlatina. Different authors make different statements as to the frequency and the time of the appearance of otitis in scarlatina. According to v. Gaessler, an author whose observations are based on the autopsies he has performed, the middle ear is affected in all cases of scarlatina, although perforation of the tympanum may not have taken place. The changes vary widely in intensity from hyperæmia of the mucous membrane with scant secretion of mucopurulent liquid, to intense swelling and infiltration, with profuse serous or purulent discharge or (in the most severe cases) thick yellow and consistent fibrinous exudate, completely filling the cavities of the middle ear. Amongst twelve post-mortem examinations only twice perforation of the tympanic membrane had taken place. The cartilaginous part of the Eustachian tube, with one single exception, was normal, which would prove that the infection spreads not by continuity from the throat, but by way of the circulation.

In the lighter cases and those of medium gravity the course is not much different from what we see in otitis complicating other infectious diseases, but in the diphtheritic cases, classed also as panotitis, rapid progressive destruction is the rule; caries and necrosis of the ossicles, and of the temporal bone, leading, according to the locality of the destroyed portion, to facial paralysis, total loss of hearing, or by spreading to the skull cavity to fatal meningitis, brain abscess or sinus phlebitis with pyæmia. The most common sequel is total loss of hearing, which when occurring in young individuals inevitably

leads to deafmutism. The percentage of deafmutes from this cause varies according to the locality, from 2 per cent. (Italy) to 27 per cent. (Norway). (Quoted from Oscar Wolf.) Fortunately, this termination is becoming rarer, according to the statements of several authors, certainly owing to the better attention given to ear complications in infectious diseases. On the necessity of watchfulness in this direction not too much emphasis can be placed, and in this connection it will be well to bear in mind that grave alterations in the middle ear may exist in a case of scarlatina, with a comparatively small changes of the drum membrane.

AN UNUSUAL CASE OF POTASSIUM IODIDE IDIOSYNCRASY.

By HENRY GATHMANN, M.D.,
MILWAUKEE, WIS.

In treating a patient, aged fifty-two years, tailor, suffering from complicated pathological conditions in and about the perineal region, I recently had occasion to administer small doses of potassium iodide for a few days. The result was, it seems to me, sufficiently remarkable to warrant its publication.

The patient had been ordered a saturated solution of potassium iodide, and took three doses of ten drops each, in water, on the first day; the dose was increased by one drop daily, so that on the fourth day he took three doses of thirteen drops each. On this day his finger tips showed a slight cyanosis, and as no reason for this condition could be found in any of the vital organs, the drug was discontinued for the entire fifth day. Although this local cyanosis thereupon disappeared within twenty-four hours, I was not thoroughly convinced that this was not a mere coincidence, and that the symptom had really been due to the iodide.

So, on the evening of the sixth day, one single dose of fourteen drops was given the patient, and next morning I found him afflicted in the following peculiar and even alarming manner: There had occurred during the night, after this single dose of fourteen grains, a diffuse ecchymosis under the entire skin of all his fingers and thumbs, so that at first sight they appeared exactly as if he had dipped his fingers, up to the metacarpophalangeal joints, into a pail of indigo dye. The discoloration stopped very abruptly at these joints, a few dark-red specks at its upper limit being noticed on closer inspection only. The fingers, in addition, were numb, cold, stiff, slightly swollen, and very painful. The little finger of each hand was most severely affected and almost absolutely black; the process lessened very slightly in each succeeding finger, so that the thumbs were of a very dark blue, rather than black color. The metacarpal region of each hand was normal in color, though just a little swollen. In addition, the extreme tip of the nose was similarly affected, though less severely. The toes, however, were and have remained entirely normal, and, in fact, excepting a few isolated, mild purpuric spots on the thighs and on one arm, the condition was confined altogether to the fingers and the tip of the nose.

Under the assiduous application of warmth and friction (and discontinuing the potassium iodide, of course), the fingers very gradually became less painful, the swelling subsided slowly (though leaving blisters on nearly all the middle phalanges), natural warmth and motion returned, and gradually the dark color faded, so that it was nearly three days before the patient and his friends felt quite reassured that the fingers and nose were safe from gangrene.

I find occasional occurrences of irregular ecchymotic spots, "mostly confined to places below the knees," and due to large doses of the drug, mentioned in literature; but nowhere have I found the description of so intense and yet sharply circumscribed an ecchymosis of such peculiar and symmetrical distribution from this drug, and especially in the small dose named. There was no gastric irritation, coryza, acne, nor any of the other symptoms of iodism.

Neither his occupation (tailor), nor his past history, nor any other circumstances seem to afford a clue why his feet should have remained perfectly normal while his fingers suffered so intensely.

Artificial Alcohol.—That alcohol may be produced by chemical combination of its elements, without recourse to the fermentation of sugar, has been known to chemists since 1860, when it was first so prepared by Berthelop from acetylene. That substance was then expensive and difficult to obtain, but now that it may be made by simply moistening calcium carbide, which in turn is manufactured on a large scale by the electrical combination of lime and charcoal, chemists are talking of a revolution in the alcohol industry. According to a recent French writer, however, this revolution is not yet upon us, for alcohol from artificial or synthetic processes cannot yet be produced so cheaply as by fermentation and distillation. So we shall still rely on nature to make our alcohol for us, for the present, confining our share in the matter to its separation from admixed impurities and dilutents.—*Success.*

The Treatment of Granulating Wounds.—Wagner believes that the conventional method of treating granulating surfaces by keeping them covered with ointment and close dressings tends to retard the growth of the epidermis and protracts the healing. For a number of years he has treated such wounds by removing the dressing each morning, cleansing the wound and then allowing it to remain exposed to the air all day. Care is taken to place the part so that it will not come in contact with the clothing etc. At night a dressing of some drying powder and of gauze is applied. Treated in this way the sprouting epidermal islands are not macerated as is usually the case, but grow vigorously and the area is covered over in a surprisingly short time. Under ordinary conditions no danger of infection need be apprehended.—*Centralblatt für Chirurgie*, No. 50, 1903.

The Fatty Degenerative Changes in Anæmia.—In the early stages of anæmia, writes Jennie G. Drennan, we find the patient seemingly well nourished, as far, at least, as the formation of fat is concerned. Later on, he becomes emaciated. Many, if not all, cases of anæmia are associated primarily or secondarily with digestive disease, whereby the proper nutriment is not prepared for the different tissues. Fatty degeneration occurs in all of these, and symptoms arise due to loss of function. Anæmia is a symptom arising as a pathological condition of one tissue of the body—the blood. The cells of the blood as a tissue undergo fatty degeneration and fail to be oxygen carriers; thus failure results in this tissue, as in all others; as a nutritional defect, the white blood cells undergo fatty degeneration. In time the blood-making organs fail to produce cells, even to undergo this form of degeneration, and also in time the other tissues of the body fail to produce cells to likewise undergo fatty degeneration; reproduction of tissue fails through lack of nutrition, even lack of pathological tissue. During the stage when fatty degeneration is active, the patient is producing a form of tissue which, although in pathological amounts, will serve as a source of assimilable food to him. During this stage he is incapacitated from normally performing the functions of the body; but if kept at rest he may exist for a long time, nourished, in fact, by his own fatty degenerated tissues, like the hibernating bear.—*International Medical Magazine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PREVENTION OF TUBERCULOSIS.

THE existence in an individual of a disease produced by a microorganism requires two conditions: (1) The presence of the virulent causative microorgansm in the tissues of the individual. (2) The susceptibility of these tissues to the action of the microorganism. If either of these factors is absent the other becomes inoperative. The prevention of bacterial diseases can therefore be undertaken from two standpoints: (1) Prevention of the causative microorganism entering the tissues. (2) Production of insusceptibility of the tissues to the action of the microorganism. The accomplishment of either of these aims brings about the disappearance of the disease. Hitherto the prosecution, of these objects, either singly or in combination, has not sufficed to prevent the presence of bacterial diseases among mankind. In the want of accurate knowledge concerning susceptibility and insusceptibility these diseases in the past have been chiefly attacked from the first standpoint. The principal means which have been utilized for this purpose are quarantine, disinfection, and the improvement of public and private hygienic and sanitary conditions. Quarantine and disinfection deal directly with limiting the dissemination and with the destruction of the causative microorganism. They therefore attack the foci of the disease against which they are directed. If perfectly carried out in any community quarantine and disinfection exterminate these foci and the disease soon vanishes. As might be expected, experience has shown that the degree to which they can be satisfactorily prosecuted is directly dependent upon the nature of the disease attacked and the number of its existing foci. If these are few in number and the nature of the disease is such that it can be promptly recognized, satisfactory quarantine and disinfection are easily instituted and the disease soon disappears. If the foci are many and the disease is not promptly recognized these measures can be less satisfactorily utilized and more time is required to reach the desired result. If the foci are indefinitely multiplied and a large number of cases pass unrecognized, quarantine and disinfection for all practical purposes cannot be satisfactorily performed, and as a result but little headway is made—the disease remains in permanent existence. An example of the latter condition is seen when we consider the prevalence of measles, scarlet fever, and diphtheria in our large cities. Here it has been found impossible to enforce any efficient system of quarantine and disinfection against these diseases because of the tremendous number of foci of infection and because many cases are so mild in character that they never come under medical attention and hence practically pass unrecognized. Thus the number of foci exterminated by quarantine and disinfection does not prevent the prevalence of these diseases. It is further evident that quarantine and disinfection when utilized for the purpose of preventing the spread of bacterial diseases are mutually dependent upon each other. Quarantine is, of course, the most important, but quarantine minus disinfection could not be expected to produce the result. On the other hand disinfection minus quarantine is at once shorn of its power. The dependence of disinfection upon quarantine is shown by considering any community in which the system of quarantine has remained the same while the system of disinfection has been altered. Under such conditions, although an advanced and scientific system of disinfection was substituted for one that was most crude and unscientific, no reduction in the prevalence of the disease attacked resulted. While quarantine and disinfection deal directly with the foci of infection, the other means above mentioned attack the problem with but very little, if any, reference to such foci. That is to say, whatever good they exert, except when their application is very limited, is exerted outside the foci of infection equally as much as at such foci. While quarantine and disinfection can only do good in the actual presence of the causative microorganism, improvement in public and private hygiene and sanitation, are applicable for use at all times and produce an equal amount of good so far as the conditions which they create are concerned, entirely independent as to whether there are many or few or no foci of infection. But the carrying out of these measures also attacks the problem from another (the second) standpoint, viz., they improve the general condition of man and hence increase his insusceptibility toward bacterial infection In no small measure is their efficiency to be ascribed to this phase of their action.

If the above statements are true their application to the prevention of tuberculosis cannot but be profitable. In its development this disease is the most insidious of the bacterial infections. Thousands of cases do not come under medical observation until months after the disease has been in progress. Its foci of infection show a greater dissemination than those of any known bacterial disease. The majority of those afflicted with it must of necessity pursue their ordinary avocations. These are a few of the conditions which surround tuberculosis: They cannot be eradicated, for to eradicate *them* means the eradication of the very nature of the disease. In their presence it is foolish to suppose that much benefit will be obtained from methods of quarantine and disinfection which are practical. This does not mean that attempts in these directions should be abandoned, but it must be realized that they are of minor importance and that their overestimation leads to a false sense of security and blinds the vision to other considerations which are important in the highest degree. If progress is to be made at the present time the chief reliance must be placed upon means which are not dependent for their efficiency upon the nature of the disease and the dissemination of its foci. The prosecution of such means should be paramount to all other

considerations. The improvement of personal and public hygiene and sanitation are the agents which to-day nearer than any other meet these requirements. There is no doubt that they must demand the chief attention of those who are endeavoring to prevent the spread of tuberculosis. Past experience and rational thinking command the acknowledgement of the truth of this statement. The more extensively they are pushed and the wider their scope the more efficient do they become. Limiting their operation to the known foci of the disease, limits their power and lessens the true appreciation of their worth in the minds of those who are at work upon the tuberculosis problem. For these reasons and because their efficiency is not dependent upon the nature or number of existing foci of the disease they should be energetically carried out in all unhygienic and insanitary locations without any regard as to whether or not tuberculous foci are there present. The results which these measures are capable of producing are only to be obtained in this way. This conception not only broadens the problem of the prevention of tuberculosis, but it brings it to a position where rational practical measures can be put into operation. Just in proportion as these measures are carried on notification of the disease becomes unnecessary. For their most complete prosecution notification is not required. Notification of a communicable disease is necessary and justifiable from two standpoints: (1) Statistical information. (2) To furnish data for attacking the foci of the disease. From the first standpoint notification becomes at once registration. It cannot be denied that the registration of tuberculosis is desirable. Without it the effect of any preventive measure cannot be properly estimated. But notification in this sense is a very different thing when it is enforced from the second standpoint. Here notification is only justifiable when the direct attack of the foci of the disease is the vital issue. Since for the prevention of tuberculosis the attacking of its foci is of secondary and very minor importance at the present day, notification is unnecessary. It is true that in certain communities where notification has been made compulsory, a decrease in deaths from tuberculosis has followed. But this is no argument that such notification was the cause of the decrease. In order to demonstrate this, it must be shown that this decrease was due to measures adopted as the result of the notification and that these measures could not have been put into operation without notification. The MEDICAL RECORD does not believe that such facts can be shown.

At the present time the powers of boards of health and all other official departments interested should be tremendously increased in the direction of enabling them to eradicate all unhygienic and insanitary conditions. Such powers they should utilize to the fullest extent. They should realize that a thousand times more is to be accomplished in these directions than can be possibly attained by directly attacking the foci of the disease. By making these measures paramount the terrorism of the tuberculous patient and his companions is swept away. His coöperation becomes enlisted. His education along the proper lines of prevention becomes not only possible but of comparatively easy execution. The aid of the public at large and the medical profession, without which no permanent good can be accomplished, becomes certain, and most important of all, the prevention of tuberculosis will be conducted along lines which are rational and which have the solid foundation of past experience.

THE COURSE OF BIRTH WITH GIANT CHILDREN.

IN the *Sammlung klinischer Vorträge* Dr. J. Ettingshaus analyzes exhaustively the experience on this subject of the Königlichen Charité at Berlin from 1895 to 1901. Among the 13,112 births, 510 were "giants," meaning thereby children with a weight of 4000 grams or over. Comparing the proportion of giants to all births at Dresden and Berlin, the percentages are 2.76, 3.45, and 3.94, respectively, with a maximum for any place and year of 4.54 and a minimum of 2.00. The picture of a giant child calls up that of a powerful, and not too young, mother, who is not a primipara. Thus, while nearly two-thirds of all mothers admitted fell below twenty-five, less than one-half of the mothers of giants fell below that age, and of the mothers of the heaviest, fifty-two, more than half were between thirty and forty. A similar result is obtained if one compares primiparæ with multiparæ. About two-thirds of the mothers of giants fall into the latter class, and in the case of the heaviest children, the number of previous pregnancies is, on the whole, the greatest. Heredity appears sometimes to enter as an etiological factor. Also the statistics reveal the presence in the mothers of giants of unusually large pelves. Respecting the length of time of delivery just in the case of the heaviest children it is sometimes unusually short. Nevertheless it is, in general, prolonged; an average for the time of expulsion being for the primiparous mothers nearly three and three-quarter hours, as against one to two hours in the normal case; and for the multiparæ one and three-quarter hours as against a normal average of one-quarter to one-half hour. And with giants an expulsion time of ten, twenty, and more hours quite often occurs. As regards the cause of delay, there is here hardly a question of contracted pelves, nevertheless the unusual size of the child makes the pelvis relatively small. In this prolongation of the expulsion time there is, perhaps, in the absence of contracted pelves, malpresentations, etc., a datum point for the diagnosis of a giant child. And this diagnosis is not unimportant, as in the case of giant children, more than others, artificial delivery is necessary. Thus in Ettinghaus's series artificial delivery was resorted to in 8.42 per cent., and in the heaviest, fifty-two, in 15.38 per cent; as against 5 per cent. in the average run of cases. The reason for this greater need of aid is the size of the child, and not primiparity (the usual cause), as here multiparity strongly predominates. Especially is the size of the head the determinant factor. And in this circumstance, involving as it does non-descent into the pelvis, we have the chief cause of the frequently observed weakness of the pains. An additional evidence that the size of the child is the determinant factor is found in the rarity of abnormal presentations. Also prolapse of the funis is less frequent here than usual, the large bulk of the child filling up the lower uterine segment. Head presentations occurred in 96.88 per cent. of the cases as against

93.47 for normal births. Lacerations of the soft parts during birth are much more frequent than in normal deliveries, especially the higher degrees of such lacerations. And among the mothers of giants, in conformity with the general experience, it is the primiparæ which suffer most from these accidents. For while the primiparæ were represented only to the extent of 26.64 per cent., they formed 49.39 per cent. of those suffering from lacerations. The general condition of the mothers during and after parturition was, in general, quite good, which is explicable by their good physique and their being, as a rule, multiparæ. As regards mortality, Dubois has found that in forty-five mothers of children over 4900 grams in weight, the mortality is relatively considerable, though it is not directly dependent upon the greater size of the child. In Ettinghaus's 510 cases there were only four deaths, but one of which was directly chargeable to the unusual size of the child. In any case the percentage of mortality was low compared with the average (0.78 per cent. as against 1.09 for normal births).

While the mortality of the mothers is thus small, the case is far otherwise with the children. For though the percentages of mortality for the normal pregnancies and births and those of giants are 8.55 and 33.92 per cent. respectively, the deaths of giants during parturition are numerous.

Thus while in normal births the percentage of freshly dead children to the whole number dead is 51.58 per cent. (and consequently that of the macerated 48.42 per cent.), with giant children the ratio of the freshly dead is 95 per cent. (and the macerated but 5 per cent.). That the mortality is incident to increased size and consequent delay in parturition, is shown by the fact that the percentages rise in steady progression with the weight of the child, from 2.79 per cent. for weights between 4000 and 4200 grams, to 25 per cent. in the case of those over 5000. As regards the proportions of the sexes, while in normal births the males are to the females as 105 or 106 to 100, with giant children the proportion is 216 boys to 100. And while the relative mortality is about 55 per cent. for boys to 45 for girls, with giants it is as 60 to 40. In Ettinghaus's series, besides those born dead, six died some days after birth; all of them had shown objective signs of severe injury, such as cyanosis or deep asphyxia. Also when born seventeen more showed signs of being more or less deeply asphyxiated but soon recovered. Turning now to the children, certainly the most striking fact is the proportion of the sexes, the results at Dresden, Munich, and Berlin, averaging about two and one-quarter times as many boys as girls, with extremes of 284 and 178 per cent. Nevertheless girls are represented in even the heaviest children, three of the heaviest eleven being girls. A surprising result is the average weight for the two sexes—namely, 4285 grams for the girls as compared with but 4204 for the boys. But v. Winckel's results agree, for he found the average weight for the four girls to be 4300 grams, while that of the twenty-seven boys reached only 4265. In his series v. Winckel found a duration of pregnancy of at least 302 days. On this last point Ettinghaus's data were not precise enough for the expression of an opinion. But the length, weight, and, above all, the considerable development of the skull, speak for a long duration of pregnancy. Not fewer than seventy-seven had a head circumference of more than 38 cm., and the several diameters were enlarged correspondingly. The author then gives a table showing the most important data in the principal cases in the literature of births of children of 5000 grams or over. The average age of the mothers is about thirty-four years, and the same law holds, as in his own series, as regards the proportions of primiparous and multiparous mothers. His experience is also confirmed in other particulars. Out of the twenty-five cases cited, the children in seven were perforated or delivered by laparotomy. Of the eighteen cases in which the fate of the child is recorded, two-thirds were born dead; eleven of the twelve dying during birth. The boys were three and a half times as numerous as the girls.

Reception Hospitals for the Temporary Insane.

The establishment of hospitals in which patients —suffering from forms of mania that skilled alienists believe to be of but a temporary nature—may be detained during a certain period for the purpose of close observation, has been advocated many times within the past few years.

Dr. Nathan Raw read a paper entitled "The Relation of Mental Symptoms to Bodily Disease," at a recent meeting of the Medico-Phychological Association of Great Britain and Ireland. In this paper Dr. Raw drew attention to the great frequency with which mental symptoms were developed in an attack of bodily illness, and to the unsatisfactory system obtaining in England of treating and dealing with persons suffering from temporary mental disorders. "It was not," he said, "his purpose to speak of organic insanity, but of those persons who in the course of such diseases as pneumonia, typhoid fever, toxic poisoning, puerperal septicæmia, exophthalmic goiter, and myxœdema required special provision in the shape of nursing and treatment, without having recourse to certification, and without placing them among those who could be correctly described as of unsound mind." The author was of the opinion that a reception hospital for mental disorders should be established in every town, preferably by the municipality, from which, if recovery did not ensue in six weeks, cases should be drafted to the asylums proper. He knew from his own experience that many persons were now sent to asylums who, if they had been accommodated in such reception houses, would have recovered, and further, would have been spared the stigma which in so many cases prevented a man from subsequently obtaining employment.

Several well-known authorities on mental disorders took part in the discussion which followed the reading of Dr. Raw's paper. Among others, Dr. J. Wiglesworth did not agree with Dr. Raw that there were so many cases of bodily disease associated with insanity. He was inclined to think that the most suitable cases for reception houses were acute alcoholics, whom he deemed just as insane as those afflicted with any other form of paranoia. He likewise urged that town was quite the wrong place in which to treat such cases. The most restful and delightful surroundings of the country were a great help to recovery. The period of detention of cases sent to receiving houses he thought should be nearer two weeks than six weeks.

Dr. Robert Jones pointed out that the period set by the London County Council was six weeks, but it could be extended more or less indefinitely by further periods of six weeks. He thought that Dr.

Raw had fully established the necessity of such reception houses, and he entirely supported Dr. Wiglesworth's contention that such houses should, at any rate, be surburban. He did not think that an asylum was the proper place to send alcoholics to. The President of the Association approved of the suggestion to establish reception houses for temporary cases, but insisted that every care should be taken that the presiding genius of such institutions should be a properly trained psychologist.

There should seem to be a growing sentiment in favor of establishing reception hospitals for the observation of those who are thought to be suffering from temporary mania. The idea has been mooted in this country, and discussed editorially in the MEDICAL RECORD some time ago, and at Albany the scheme has been carried into effect.

THE PILL HABIT IN THE UNITED STATES.

The patent medicine habit is strongly developed among Americans, and appears to be advancing by leaps and bounds. Pill-taking is the most popular form of drug indulgence manifested by the inhabitant of this continent, and the number of pills manufactured in the course of a year is so large that the magnitude of the figures is almost beyond the grasp of human intellect. The immigrant to these shores is generally adaptable, and on becoming a citizen quickly falls into the customs of his adopted country and cheerfully swallows his quota of pills and the various other remedies warranted to cure or to alleviate all the ills to which human flesh is air In *Leslie's Monthly Magazine*, January, is an article which describes the American pill at length. The statement is therein made that the manufacture of pills is increasing at the rate of 20 per cent. each year. In other words, there will be a fifth more pills eaten in the United States this year than last, and a fifth more next year than this. American women are declared to be responsible for this ever-growing consumption of pills, and it is asserted that next to candy and beauty washes pills take the first place in the affection of the female sex in this country. Of course, pills are made for every kind of complaint, and in Detroit, the metropolis of the world for pill manufacture, nearly seventeen hundred kinds are turned out, and the writer of the article referred to is so unkind as to asseverate that the American woman tries most of them at one time or another of her life. An excellent account is given of the money spent and the journeys undertaken into unknown and tropical countries in the search for new drugs with which to make pills. A sketch is also given of the methods of manufacture, and the statement is made that at one of the large pill factories in Detroit there is a machine which grinds out 2,000,000 pills a day. Probably the physician has no cause to grumble at the immense consumption of pills, for there can be but little doubt that a habit indulged in, as is the pill habit, will, in the course of time, bring its devotees into his hands. Excess of any substance ingested by a human being will inevitably lead to untoward results, and a wholesale use of pills must, in the nature of things, undermine the strongest constitution.

THE PROLONGATION OF LIFE.

From the earliest times the aim of men has been to lengthen the span of his years upon earth, and even to attain to immortality. The alchemists of old spent time and money unsparingly in the futile effort to discover the elixir of life, and although present-day scientists have abandoned this fruitless search, yet various means of prolonging existence are ever being promulgated. It is now known that by paying strict attention to the laws of health that longevity is generally attainable, and literature in which rules for rational living are laid down, appears with undeviating frequency. Dr. Hermann Weber recently delivered a lecture of this nature before the Royal College of Physicians, London. In the first place he pointed out that the diminution of infant mortality and the improvement of the hygienic conditions of towns and houses have raised and will continue to raise, the average duration of life. The speaker from his own experience, gave his views as to the best measures to pursue in order to reach a green old age. Among other matters upon which he dwelt was the importance to the digestive system of paying due regard to the action of the bowels. Attention was drawn to the fact that the quantity and quality of food play a conspicuous part with persons who suffer from constipation. Indeed eating wisely is essential, if an individual intends to overcome the evil results of sluggish bowels. The conclusions reached by Sir Hermann Weber as to the scheme of life to be observed so that one's days may be long in the land is as follows: Moderation in eating and drinking and physical indulgence. Pure air out of the house and within. The keeping of every organ of the body, as far as possible, in constant working order. Regular exercise every day in all weathers; supplemented in many cases by breathing movements, and by walking and climbing tours. Going to bed early and rising early, and restricting the hours of sleep to six or seven hours. Daily baths or ablutions, according to individual conditions, cold or warm, or warm followed by cold. Regular work and mental occupation. Cultivation of placidity, cheerfulness, and hopefulness of mind. Employment of the great power of the mind in controlling passions and nervous fear, strengthening the will in carrying out whatever is useful, and in checking the craving for stimulants, anodynes, and other injurious agencies. While Sir Hermann Weber's lecture contains nothing that has not been said before, a recapitulation of the measures to be taken to lengthen our term of existence here cannot but do good. The life led nowadays by the ordinary citizen is not conducive to longevity, and although good advice as a rule falls on barren ground, yet if even a few seeds alight on fertile soil and flourish, the words of wisdom spoken will not have been entirely wasted.

THE PREVAILING PNEUMONIA AND ITS CAUSES.

The unusual prevalence of pneumonia in New York, and the mortality occasioned thereby, has naturally brought forth much discussion concerning the disease and the means of prevention and cure. Especially has the question of its causation been made the subject of debate, and it must be said of a certain amount of theorizing. By some medical men the somewhat virulent infectiousness of acute pneumonia would seem to be regarded as an established fact, a view of the matter scarcely warranted by our present knowledge of its bacterial etiology. That the malady is communicable under certain conditions has been established with certitude. But so far as the mode of communication is concerned definite information is lacking. As Dr. Klebs of Chicago truly says, "We presume, and probably correctly, that the infective germ is contained in the expectoration, and in prophylactic efforts we will always bear this in mind. But the fact that outside of a few reported epidemics we have but rare evidence of its spread within one family or from one individual to another, forces upon us the disbelief in its marked infective powers."

Few physicians will be found who will deny that tuberculosis, according to the result of investigations into the cause of the two diseases, must be looked uponas more infectious than acute pneumonia. Yet there are many men of world-wide reputation. who are of the opinion that the infectiveness of consumption has been greatly exaggerated. For example, Prof. C. Fraenkel of Halle recently stated his views on the subject as follows:

"Tuberculosis is a house disease. Not in the open air is it transferred, and even when favorable conditions are given for infection—as, for instance, among street sweepers—in not a single instance has such an event been directly associated with the alleged cause. In the face of exaggerated and entirely unfounded fears to the contrary, this fact cannot be stated often enough, and not precisely enough. It is inside the house among families, in factories, workshops and prisons, among people who live, work and sleep in badly kept and uncleaned rooms, that infection takes place. As soon, however, as once the bacilli has passed the threshold of the house it has lost its terrors, and only in exceptional cases may find its way again into the human organism."

Improved hygienic measures have checked the spread of tuberculosis, but have exercised no favorable influence on pneumonia. On the contrary, pneumonia has increased, tending to show, in a more or less conclusive manner, that hygiene, sanitation, and the adoption of antiseptic principles have but little to do with checking the widespread dissemination of the disease.

The truth is that further knowledge as to the bacteriology and epidemiology of pneumonia must be gained ere authoritative statements with regard to its direct causation can be recognized. Regulations to stop expectorating in public are excellent, and should be enforced as strictly as possible, both in the interests of decency and the general health. On the other hand, the tendency to alarm the community with statements concerning the absolute infectiousness of diseases, the etiology of which are not definitely known, is perhaps carrying the matter too far.

The Treatment of Nephritis: Some Recent Suggestions.—Thomas J. Harder reviews a number of recent books and articles on the subject. In treating of acute nephritis Van Noorden gives the following dietary: *To be avoided*, because of creatinin produced, meat extracts, meat broths, eggs; because of pigments produced, foods containing hæmoglobin; because of hippuric acid produced, green vegetables. *To be given sparingly*, because of urea and sulphates produced, milk; because of irritant effect during excretion, water. *To be given with impunity* in all but severe cases, because no injurious end-products are produced, cream, butter, white vegetable soups, puddings made from oatmeal, flour or maize, white bread. To neutralize the bad effects of the phosphates in milk, a little calcium carbonate is added. This enables the phosphates to be got rid of in the fæces. In contracted kidney he gives a fairly liberal diet, but a limited amount of water—about two and a quarter pints *per diem* of ingested fluid. Widal and Javal hold that salt is, for certain cases of tubular nephritis, a dangerous constituent of food, and propose a "cure by dechlorination" for such cases. In functional albuminuria G. Lyon recommends rest in a horizontal position for an hour after meals. In the management of the uræmic state the value of venesection is attested by several observers. Diaphoresis seems to be of use only when followed fairly quickly by diuresis. Several authors uphold the value of operation in certain cases of Bright's disease.—*The Practitioner.*

News of the Week.

The Prevalence of Pneumonia.—The Advisory Board to the Health Commissioner of New York has given out a statement to the public regarding the danger from pneumonia and the best means to avert it. The principal stress is laid upon the bacterial causation of the disease and the consequent danger of spitting elsewhere than in suitable receptacles and of stirring up the dust in private and public buildings. Concerning this last point the statement concludes: "The Advisory Board would urge upon the Health Department the desirability of instructing, in the proper methods of dust disposal, all those who have in charge the duty of cleaning public institutions, such as court-rooms, police stations, hospitals, dispensaries, churches, theaters, public conveyances, etc., as well as those responsible for factories, stores, offices, and the like, and commends the matter to the attention of all householders, to whom, not less than to inmates of public institutions and places of assembly, the risks of dust infections are at this time of especial significance."

Smallpox Increasing in Philadelphia.—For the week ended January 23 there were reported to the Philadelphia Bureau of Health 106 cases of smallpox, with 13 deaths, as against 58 cases and 24 deaths for the preceding week. This is the largest number for any week in three years. The total number of deaths was 618, as compared with 736 for the preceding week.

Smallpox in Indiana.—Fifteen counties in Indiana have reported cases of smallpox to the State Board of Health and the number of cases is double that of the corresponding time last year. The cases are also of a more malignant character. The situation in Spencer and Clay counties is most serious.

Unvaccinated Children in Schools.—Judge Mower of the Common Pleas Court, Springfield, Ohio, has handed down a decision in the mandamus suit brought by George W. Crowell to require the Board of Education to allow his son to attend school even though he is not vaccinated. Judge Mower held that the ruling of the board to this effect could not be sustained by law, inasmuch as it was only applicable to times when there is an epidemic of smallpox.

Phthisiophobia in Australia.—It is stated in a despatch from Sydney, N. S. W., to a London newspaper that the Board of Health of Melbourne, Victoria, has decided to treat consumption as an infectious disease and to isolate all sufferers. It has arranged to accommodate a number of consumptives at the quarantine station.

Another Victim to Laboratory Plague.—A press despatch from St. Petersburg says that the chief of the Bacteriological Laboratory of the Imperial Institute of Experimental Medicine died of the plague January 20. He became ill January 16, after an inoculation with living plague cultures, and repeated injections of anti-plague serum were unavailing. All who had been in contact with him have been treated with anti-plague serum, and the staff of the laboratory, which is situated at Fort Alexander, on a small island, has been isolated.

The Cincinnati Research Society has elected the following officers for the year: *President*, Dr. David I. Wolfstein; *Vice-President*, Dr. A. Knight; *Secretary and Treasurer*, Dr. Samuel Iglauer. The Executive Committee consists of Drs. Wolfstein, Iglauer, Knight, Heidingsfelt, and Kramer.

To Stamp Out Bovine Tuberculosis.—On the initiative of Professor Behring, a bill will probably soon

be introduced in the Reichstag, enjoining the inoculation of all calves with his specially prepared tuberculosis vaccine. The measure is not favored by the supporters of Koch's view regarding the non-identity of bovine and human tuberculosis, as the vaccine is made from human tubercle bacilli; but Professor Behring has earnestly pleaded the adoption of an imperial law to this end in conference with the Minister of Agriculture, and it is thought his arguments may prevail.

Inspection of Chicago Hospitals.—A rigid inspection of private hospitals with reference to their precautions against fire has been undertaken by the city of Chicago. The inspection undertaken in the Spring of 1902 was made by the Building Department alone; the one now being made is under the joint direction of that department and the Department of Health, a building inspector and a medical inspector working together in each investigation, and making joint reports to each department. In this way it is hoped to secure better results in the matter of prompt remedy of defects discovered.

Ohio State Board of Health.—At a meeting of the Ohio State Board of Health at Columbus, Dr. M. C. Chapman of Toledo read a paper on "The Pollution of Our Water Supply." Chas. T. Dumont of Norwood, O., discussed "Needed Sanitary Legislation," Dr. C. L. Wilbur of Lansing, Mich., discussed "Collection and Registration of Vital Statistics." Dr. L. K. Baker of Cleveland and Dr. H. C. Rutter of Columbus also read papers.

The San Francisco Board of Health.—Drs. John V. Hughes and W. A. Harvey have been appointed members of the Board of Health of San Francisco.

Dr. N. Senn sailed from San Francisco, January 7, for Tahiti, whither he goes to join a commission appointed by the French Government to investigate the diseases of the island.

Dr. D. D. Crowley of Oakland, Cal., member of the State Board of Health, has been appointed Surgeon-General of the State Militia.

The Medical Society of Alameda County, California, at a meeting held on January 12, elected the following officers for the ensuing year: *President*, Dr. J. Maher; *Secretary*, Dr. A. H. Pratt; *Treasurer*, Dr. C. A. Dukes.

A Milk Trust in Chicago.—It is announced that a company, capitalized at $4,000,000, is being formed to control the milk supp y of Chicago. The purpose of the company, as it is stated, by the promoters is not to advance prices, but to raise the standard of milk, which will be certified as free from bacteria. It is promised that the price of such milk will be only seven cents a quart.

The Pure Food Bill Favorably Reported.—The Hepburn Pure Food bill, which passed the House at the last Congress, was ordered favorably reported by the House Committee on Interstate and Foreign Commerce on January 16. The bill as reported contains the present law regulating the importation of foreign food, passed in the last Congress. The bill provides for the exercise of federal jurisdiction over food products which enter into interstate commerce, prohibiting adulterations and misbranding.

Philadelphia County Medical Society.—At a stated business meeting, held January 20, the following officers were elected for the ensuing year: *President*, Dr. Roland G. Curtin; *First Vice-President*, Dr. B. Franklin Stahl; *Second Vice-President*, Dr. Charles P. Noble; *Secretary*, Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Ross H. Skillern; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. H. St. Clair Ash; *District Censor*, Dr. Albert M. Eaton. Also delegates to the Medical Society of the State of Pennsylvania and a large number of members were elected, and reports of directors, secretary, treasurer, censors, publication committee, committee on changes in by-laws and committee on increase in membership were read.

New Secretary of Texas State Medical Association.—Dr. John T. Moore of Galveston has been appointed Secretary of the Texas State Medical Association, to fill the unexpired term of Dr. H. A. West, who recently died.

The East Side Physicians' Association is the name of a new medical organization recently founded in this city. At a recent meeting the following officers were elected: *President*, Dr. Ignatz Morway Rottenberg; *Vice-Presidents*, Drs. Maurice J. Burstein and Fredric N. Wilson; *Secretary*, Dr. Nathan Friedman; *Treasurer*, Dr. Maurice Caspe.

Stanford University is just recovering from an epidemic of diphtheria that broke out among the students early in December.

Medical Jurisprudence Society of Philadelphia.—At a stated meeting, held January 18, Dr. D. J. McCarthy read a paper entitled "The Conduct of Medical Investigations in Medicolegal Cases at Vienna, with Special Reference to the Laboratory Work." W. Smithers, Esq., read a paper entitled "Criminal Law Procedure in Continental Europe." The following officers were elected for the ensuing year: *President*, Judge W. Ashman; *Secretary*, Dr. Henry Leffmann; *Treasurer*, Paschal H. Coggins, Esq.

Higher Tuition Fees at Columbia.—It is announced that the trustees of Columbia University have decided to increase next fall the tuition fees in the College of Physicians and Surgeons and the schools of applied science. The increase will be from $200 to $250 a year. Another change is announced by which students in these schools who are not candidates for degrees will have to pay $25 a year for each hour of weekly attendance in the various lecture and recitation courses.

A Red Cross Inquiry.—Mr. Daniel of Virginia has introduced a resolution in the United States Senate directing the Secretary of State to inform the Senate whether or not the Department of State has made the following or similar inquiries of foreign governments respecting the Red Cross Society; and, if so, what replies, if any, have been received: What financial support, if any, does the government give to the Red Cross Society? Does the government appoint any of the officials or directors of the Red Cross Society? How is the society organized in respect to its equipment for active field work? How is the executive and office staff organized? What sources of income and revenue other than the government provides? How are its accounts kept and audited? What check, if any, is provided to protect the funds of the society against carelessness and dishonesty on the part of its agents in the field? What is the extent and character of government supervision respecting the organization, finances, and work of the society? Has the society the confidence of the leading people of the country? Does it receive valuable money contributions from private sources?

A Review of Medical Progress.—The January issue of the *Interstate Medical Journal*, of St. Louis, is devoted to a carefully planned and excellently executed review of the progress of medicine during the year just past. The entire subject is divided into twelve chapters, the titles of which and the writers (who are also editors of the journal itself in their respective departments) are as follows: "Internal Medicine," by Jesse S. Myer; "Surgery,"

by Willard Bartlett; "Therapeutics," by Albert E. Taussig; "Pathology and Bacteriology," by Carl Fisch; "Gynecology and Obstetrics," by Hugo Ehrenfest; "Pediatrics," by Alfred Friedlander; "Orthopedics," by Malvern B. Clopton; "Neurology," by Sidney I. Schwab; "Genitourinary Surgery," by H. McC. Johnson; "Dermatology and Syphilis," by Martin F. Engman; "Laryngology and Otology," by William E. Sauer; "Ophthalmology," by John Green, Jr. These subjects are handled in an interesting manner by the authors, and together they constitute a most instructive epitome of the medical world's work during the past twelve months.

College of Physicians of Philadelphia; Section on General Medicine.—At a stated meeting, held January 11, a symposium was held on "The Early Manifestations of Cirrhosis of the Liver," Dr. W. W. Ford of Baltimore, discussing the "Pathological Anatomy," Dr. David L. Edsall, the "Clinical Chemistry," and Dr. Chas. G. Stockton of Buffalo the "Clinical Manifestations." Dr. Ford detailed the results of an analysis of the post-mortem findings in forty-nine cases of cirrhosis of the liver studied among the first 500 autopsies made at the Johns Hopkins Hospital. The most common associated conditions were disease of the heart and of the kidneys and arteriosclerosis. A variety of other conditions were present in individual cases, such as ulceration and suppuration. In some there had been antecedent typhoid fever and other infectious diseases. Experimental investigation has shed little light on the etiology of cirrhosis of the liver, diphtheria, typhoid fever, and other infectious diseases, causing focal necrosis of the liver, but not cirrhosis. Excessive indulgence in alcohol and malarial infection are, clinically, the most common antecedent conditions, but with alcohol alone it is not possible to induce cirrhosis of the liver in lower animals. Better success has attended the employment of butyric, lactic, and other acids. Therefore, there must be some additional factor, perhaps toxic, possibly infective, necessary for the development of the disorder. Dr. Edsall pointed out that none of the chemical tests could be depended upon to furnish aid in the early diagnosis of cirrhosis of the liver, the functions of the liver being so complex and its secretion not being accessible in a pure state. Dr. Stockton pointed out that the development of the grosser changes of cirrhosis of the liver must be preceded by a period in which functional disturbances occur, and these must give rise to clinical manifestations, which may, however, not be distinguishable from those due to associated disorders. Among these may be mentioned a sense of weight and distress in the right hypochondrium, tenderness on manipulation over the liver, digestive derangement, sallowness of countenance and the hepatic facies, headache, languor, etc. The discussion that followed, and which was participated in by Drs. James Tyson, John H. Musser, Hobart A. Hare, James M. Anders, Robert N. Willson and Alfred Stengel, disclosed the difficulty of recognizing cirrhosis of the liver in its earliest stages. Often the presence of the disorder can only be suggested, and many years sometimes pass before the disorder is fully developed, and not rarely when suspected it fails to materialize. At the close of the meeting a reception was tendered the speakers of the evening.

Obituary Notes.—Dr. EDMUND ANDREWS of Chicago died on January 22. On January 17 he was operated upon for stone in the bladder, and bore the operation well, but five days later was attacked with cardiac paralysis, and soon expired. For forty-eight years Dr. Andrews was engaged in the practice of surgery in Chicago, retiring two or three years ago. He was born in Putney, Vt., April 22, 1824. He removed with his parents to Detroit, Mich., in 1840, and was graduated from the Literary Department of the University of Michigan in 1849. Three years later he completed a course in medicine at the University, and came to Chicago. In 1857 Dr. Andrews occupied a professorship in Rush Medical College, and taught there for three years. At that time only two years' study were required for graduation, and advocating a longer course, Dr. Andrews with five other physicians, established Lind University. The University was the first to require a four-year course. In 1860 the college was absorbed by the Northwestern University, and Dr. Andrews was appointed professor of surgery. He was a surgeon in the Civil War. In 1854 he founded the Chicago Academy of Sciences, and for many years was one of its most active supporters.

Dr. VIRGIL M. D. MARCY died suddenly at his home, in Cape May, N. J., on January 21, aged eighty-one years. He was born in Cape May January 5, 1823, was graduated from Yale in 1844, and two years later from the medical department of the University of Maryland.

Dr. EDWARD B. DANA, Jr., died at his home in Metuchen, N. J., on January 21, of pneumonia. He was forty-three years of age, and was graduated from the medical department of Columbia University in the class of 1889. He was president of the Board of Health and of the Board of Education.

Dr. J. VARNUM MOTT died suddenly of heart disease at his home in Boston on January 23. He was born in this city fifty-three years ago and was graduated from the College of Physicians and Surgeons in the class of 1872. After practising here for a few years he went to Boston to live. He retired from active practice about ten years ago.

Dr. NEEDHAM M. WILSON died in Philadelphia on January 19, at the age of sixty-seven years. He was a graduate of Jefferson Medical College in the class of 1865.

Dr. ALBAN SPOONER, Jr., died at Beverly, N. J., on January 18 at the age of twenty-four years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. L. H. STAHLE of San Francisco, formerly physician to the County Hospital, died January 6, from the inhalation of illuminating gas. In a note which he left for the coroner he admitted suicidal intent and grimly remarked that the quality of the gas must have been improved, since he had inhaled it for more than an hour without effect.

Dr. FRANCIS RUDDEROW died in Philadelphia on January 23, at the age of forty-two years. He was graduated from the medical department of the University of Pennsylvania in 1884.

Dr. D. N. CONNOR died in Philadelphia on January 22, at the age of fifty-nine years. He was born in Delaware and was for a time a school teacher. He was graduated from the medical department of the University of Pennsylvania in the class of 1867.

Dr. B. G. DYSART of Paris, Mo., died at his home on January 16 at the age of seventy years. He was a graduate of Jefferson Medical College in the class of 1859. He was prominent in Masonic circles and was a member of the Missouri State Board of Health and ex-Surgeon of Cockrell's brigade in the Confederate Army. He was in active practice until the day before his death, succumbing to an attack of pneumonia following exposure while making a professional visit.

THE TUBERCULOSIS EXPOSITION IN BALTIMORE.

(Specially Reported for the MEDICAL RECORD.)

THE tuberculosis exposition, by means of which during the present week a sanitary object lesson of exceeding value has been presented to the citizens of Baltimore, opened on Monday evening, January 25, at the McCoy Hall, Johns Hopkins University, Dr. William S. Thayer presiding.

His Excellency Edwin Warfield, Governor of Maryland, made the opening address, and it was the first time he had appeared in public in his official capacity as governor. He said that the Legislature in 1902 had authorized the appointment of a tuberculosis commission to investigate the prevalence, distribution, causes, and treatment of tuberculosis in the State of Maryland, and to determine its relation to the public health and welfare and to devise ways and means for restricting and controlling the disease. He believed in arousing interest in this humanitarian work and in demanding proper legislation, and said that he would gladly cooperate in bringing about these ends. He congratulated the commission upon the success that had attended their efforts.

The Hon. Robert McLane, Mayor of Baltimore, welcomed the many distinguished guests. He pleaded for the popularizing of the work done by the commission, for it was only by bringing home to the people the necessity for a hospital for the care of infectious diseases that an appropriation could be obtained from the State. It would be a great economic advantage to the State to assist in this movement, and he urged that the present Legislature should not be allowed to adjourn without doing something to this end.

Dr. William Osler delivered a short address in which he referred to the seriousness of tuberculosis and the deplorable condition of Baltimore with regard to its inability to care for patients afflicted with contagious or infectious disease. He stated that the object of the exposition was to arouse the people from their apathy and to awaken public sentiment in behalf of the suffering hosts and endangered thousands.

In the paper of the evening, entitled "The Statistical Laws of Tuberculosis," Mr. Frederick Hoffman of Newark, N. J., said that any attempts to deal successfully with the problem of tuberculosis prevention must proceed along lines of a comprehensive statistical investigation, for the laws and tendencies of this disease were most intelligently expressed by statistical averages reduced to a uniform basis readily susceptible of critical analysis. The mortality from tuberculosis had progressively declined in American cities for more than a century. It was his opinion that the decrease in the mortality from tuberculosis in past years, or previous to 1890, must be primarily ascribed to a profound change for the better in the mode of life of the masses, such as improvement in the housing of the masses of population in the cities, providing more light and better ventilation in tenements and dwellings, less overcrowding, less intemperance, improvement in feeding infants as well as adults, improved economic conditions, especially in the way of higher wages and shorter hours of labor, the doing away with child-labor, the doing away with unwholesome and insanitary conditions of factory life, the improvement in the school life, and the general social improvement of the mass of population, making for a higher standard of life, a more deliberate view of life and the worth and value of living. Mr. Hoffman took up at length the statistical laws which underlay the occurrence of tuberculosis in modern life [illegible] neral rule, the observations and conclusions were limited to the mortality from consumption of the lungs which formed approximately about 96.5 per cent. of the total mortality from tuberculous disease. The mortality from consumption in the United States had decreased from 25 per 10,000 in 1890 to 19 in 1900. The mortality was greater in cities than in rural districts (20 per 10,000 against 13). The decrease in the mortality during the decade had been 6 per 10,000, against not quite 5 for rural districts. The mortality was greater among men than among women. The mortality among males in cities was 21 per 10,000 against 16 for females, a difference in favor of females of 5 per 10,000 of population. In country districts the death rate was 12 for males and 14 for females, a difference of 2 per 10,000 in favor of males. The decrease in the mortality during the decade 1890–1900 was 5 per 10,000 for males and 6 for females. The death rate was extremely high among the colored population. In 1900 the death rate of the white population was 17 per 10,000 against 49 for the colored. The higher mortality of the negro population from consumption and other tubercular disease was unquestionably primarily the result of race. The wide variation in the mortality of the two races from this disease remained practically the same and was practically unaffected by the more favorable conditions under which the present negro population lived. The native white population of native stock experienced a death rate considerably lower than the general average. The greater death rate among women in rural districts he ascribed to the after-effects of pregnancies, less properly taken care of there than in cities. The relative decline in the death rate had been most pronounced at the comparatively unimportant age period of sixty-five and over, while the decrease had been least at the age period when the commercial and economic value of human life was highest. Conjugal conditions modified profoundly the mortality from various causes. Males at ages 15–44 showed the highest death rate from consumption among the widowers, and at ages 45 and over among the single. The high death rate of the former he attributed to the probable transmission of the disease from wife to husband. The death rate was highest among widows at ages 15–44 and among the single women at ages 45 and over. Both sexes showed the lowest death rate among the married at practically all periods of life. Married women at the child-bearing period, 15–44, experienced a higher death rate from consumption than married men. Widowers at all ages showed a greater mortality when comparison was made with the mortality of widows of corresponding ages. An anomaly was noted, in marked contrast to the general law of mortality, that the death rate among widowers was highest at the youngest ages, while lowest at the most advanced period of life. This probably warranted the conclusion that the higher mortality of widowers at early ages was the result of disease transmitted from wife to husband. Males in all occupations experience a mortality from consumption of 24 per 10,000. In the professional occupations the mortality was quite low, being 12 for clergymen, 14 for lawyers, and 17 for physicians. Persons in the mercantile and trading class experience an average death rate of 17 per 10,000, hotel keepers and boarding-house keepers a rate of 21, saloon and restaurant keepers a rate of 29, barbers and hairdressers, 33; laborers, 37; bookkeepers, 40; servants, 43; printers, 44; cigarmakers, 48, and stonecutters, 54. The mortality in the United States was highest during March, April, and May, and lowest during August, September, October, and November. The mortality from tuberculosis varied greatly in different localities,

and he questioned seriously whether these differences were the result of climate rather than of material differences in the age, sex, race, nativity, and occupation distribution of the population. The census data were not published in sufficient detail to permit of a rearrangement of the mortality by geographical sections of the country, according to latitude and longitude, or with reference to certain topographical features, such as location of cities on lakes, in river valleys, at high altitudes, etc. A study of the relation of consumption to the elements of climate confirmed the view that certain climatic elements favor and others materially hinder the development of the disease. It was generally conceded that the mortality was highest in localities with a damp soil or a clayey subsoil, making natural drainage difficult. It was reasonably safe to say that the death rate decreased with increasing altitude, and that it decreased with increasing dryness of the atmosphere. Consumption was much more common among the poor than the rich, and this he attributed to imperfect or unsatisfactory diet. The mortality was lowest among the Jews, whether due to their dietary laws or not he did not venture to say. People who are predisposed to consumption are almost invariably persons of inferior physical development, with evidences of imperfect nutrition, resulting in a body weight about ten pounds below the average. The earlier belief in the possible heredity of consumption he believed to be overestimated except in so far that a physical constitution predisposed to consumption, and this was often transmitted from parent to child. The average duration of the disease from the time of infection to the time of death was usually given as two years, but no definite law was known to him which would warrant any final conclusions regarding this point.

His object in presenting for consideraton the general statistical laws of tuberculosis was to emphasize the need of a broad basis of sound knowledge for any far-reaching sanitary or other measures which might be adopted for the purpose of diminishing by associated effort the largely preventable amount of disease and mortality from tuberculosis. The facts would seem to warrant the view that it is possible to so localize the mortality from tuberculosis that an energetic campaign against consumption was practically certain to produce far-reaching results. If a campaign was determined upon against consumption, as it was found to occur among persons in certain recognized unhealthy employments, or under certain ill-health-producing conditions, there was no doubt in his mind but that within a few years a marked diminution in the death rate would result from such well-directed and intelligent efforts. By *preventing* the disease in the first place, it will not be found necessary to erect immense and costly institutions for the *cure* of the disease. He was certain, from a careful study of the facts in the case, that such efforts should be primarily directed against insanitary workshops, ill-health-producing occupations, and the employment of physically unfit types of man in industries in which the death rate from consumption was extremely high. By adopting intelligent measures in clear recognition of the laws which determine a high or low mortality from this disease, he felt sure that a large proportion of the present mortality would be done away with.

The Exposition.—A visit to the Exposition revealed the amount of work that had been done by the commission. The exhibit of statistics taught the undisputed supremacy of tuberculosis among the preventable causes of death. Its relation to other diseases was shown in a graphic manner by a display of charts and diagrams, in which were considered race, age, sex, occupation, heredity, marriage, food, drink, dwellings, wages, etc. Another exhibit showed the relations of factory, tenement and sweat shops to tuberculosis with an interesting collection of photographs. One of the most striking contributions to this exhibit was from the "Lung Block" in New York. The tuberculosis committees of Chicago, New York, and Boston were large contributors. The exhibit of State and municipal prophylaxis was very interesting, showing the great activity of boards of health in the modern crusade against tuberculosis. The models and pictures of the sanatoria and dispensaries covered this part of the subject most fully. The most important part of this collection showed the results of sanatorium treatment in America, England, and especially in Germany, where the sanatorium has become a governmental appurtenance, and has restored a large number of consumptives to the ranks of wage-earners. Here one learned, too, that the sanatorium was but a relatively small part of the available resources in the treatment of tuberculosis. Besides the illustrations of sanatorium life in all its details, the models and pictures showed what means were everywhere within the reach of the consumptive, Here one could see what was being done by certain federal departments, by cities, by organized charities and voluntary associations in various parts of the country. The colony idea, the roof garden, the fire escape, the veranda—all these things were shown converted to the use of the consumptive. The Committee on Home Treatment and House Hygiene had a furnished room where even the minutest details of the subject were illustrated.

Of particular interest was the collection of books and portraits cover.ng the history of tuberculosis. It was, perhaps, the most complete library on tuberculosis ever collected, and much credit was due Dr. Osler and Dr. Jacobs for their efforts in collecting and arranging this department of the Exposition. In original manuscript were found the writings of Villemin, who, in 1868, established experimentally the contagiousness of consumption. Cohnheim repeated Villemin's work in Berlin and substantiated his results. Hippocrates (Latin Edition Princeps, 1525) gave a description of phthisical tabes or pulmonary consumption. Also, a description of the form of the chest in tuberculous persons. Galen (Methodus Medendi) recommended a milk diet and dry air. Franciscus Sylvius (1614–1672) was the first to describe tuberculosis of the lungs. Celsus gave a description of the varieties of consumption or tabes. Celsus' book was open at the page on which was advocated a change of air and a long sea voyage. The pathological and bacteriological exhibit was of great interest. In it were shown a number of specimens, models in wax and cultures.

Addresses.—Each evening during the week a popular address was delivered by some well-known phthisiologist. These addresses were: on Tuesday, by Dr. Lawrence F. Flick of Philadelphia, on "House Infection of Tuberculosis;" on Wednesday, by Dr. Mazyck P. Raverel of Philadelphia, on "Bovine Tuberculosis, a Factor in Human Tuberculosis;" also, an address by Dr. D. E. Salmon of Washington, on "Some Observations on the Tuberculosis of Animals;" on Thursday, by Dr. S. A. Knopf of New York, on "Pulmonary Consumption and the Possibilities of Its Eradication through the Combined Action of a Wise Government, Well-trained Physicians, and an Intelligent People;" on Friday, by Dr. George J. Adami of Montreal, on "Facts, Half-truths, and the Truth about Tuberculosis." For Saturday the program announced a lantern demonstration by Drs. William H. Welch and Chas. H. Potter.

(From Our Special Correspondent.)

SEWAGE AND SHELL-FISH—MICROORGANISMS AND RHEUMATISM—OXFORD MEDICAL PROFESSORSHIP—UNIVERSITY INSTITUTE OF MEDICAL SCIENCE—KING'S COLLEGE HOSPITAL—DEATH OF MR. KNOWSLEY-THORNTON.

LONDON, January 8, 1904.

LAST night the fourth report of the commissioners appointed to inquire into the treatment and disposal of sewage was issued as a Blue Book. This part deals with the pollution of tidal waters, especially in reference to the contamination of shell-fish. The commissioners declare their conviction that a considerable number of cases of enteric fever and other diseases are caused by sewage contamination of shell-fish; but they do not think it possible to make an accurate estimate of the number, for though in some towns the medical officers of health have collected all available data it cannot be said that this has been done throughout the kingdom. The remedies suggested are (*a*) purification of the sewage before its discharge into tidal waters; (*b*) seizure and destruction of unwholesome shellfish exposed for sale; (*c*) setting up a competent authority to deal with all tidal waters, with power to control foreshores, close dangerous beds, pits, ponds and layings, and in some circumstances, to require treatment of sewage. The advance of knowledge may make it possible to devise a method of treating sewage by which its dangerous qualities may be eliminated, but no method at present known can render it safe to discharge in the neighborhood of fish layings. The commissioners are of opinion that no general enactment as to treatment of sewage or seizure of unwholesome fish will meet the case. The remedy must be sought in the waters, pits, ponds, and layings themselves. The commissioners are convinced that the only way to meet the evil is by placing all tidal waters under the jurisdiction of competent authorities with full power to regulate the taking of fish and to make all restrictions required for the public safety. These powers they propose to confer on the river's boards, subject to appeal to a central authority. As to foreign shell-fish, it is recommended that a guarantee be required on the part of the governments concerned, that the fish have not been procured from localities where they would be liable to contamination by sewage or other filth.

Rheumatic fever was the subject of a further communication by Drs. Poynton and Shaw, at the Pathological Society. They opposed the idea that the disease might be a sort of attenuated pyæmia, and held that it has as definite clinical entity—quite as much as tuberculosis. They relied entirely on fatal cases for argument. They showed that the diplococcus rheumaticus could be easily distinguished from the staphylococcus aureus. In twenty-five cases of fatal rheumatic fever the staphylococcus was not found in cultures or in the lesions; when this organism was found the condition was not rheumatism. Experimental injections into animals were made; the staphylococcus produced septicæmia or pyæmia with multiple abscesses or no result; the diplococcus rheumatic fever or no result. Injections were then made with mixed organisms. When these were made simultaneously death was rapid, pyæmic abscesses containing the staphylococcus were formed and arthritis was also produced and in some cases endocarditis. Both organisms were demonstrated in the tissues and isolated after death. A clinical case was described which was studied by Drs. Paine and Poynton. It was that of a boy who had cellulitis of a leg and developed arthritis and pericarditis. After death purulent pericarditis, arthritis, and multiple abscesses were found and Dr. Paine isolated from the pus the two organisms. The paper was fully illustrated by drawings, lantern slides, and cultures. The conclusions submitted were: (1) the staphylococcus is not a cause of rheumatic fever, either in simple or mixed infection; (2) rheumatic fever is not an attenuated pyæmia so far as the staphylococcus aureas is concerned.

Dr. Burdon Sanderson is resigning the Regius Professorship of Medicine at Oxford, and there is subdued excitement as to his successor. Oxford graduates met in unusual numbers to discuss the vacancy. It was commonly reported that the Reader in Pathology would be appointed and hold both offices for the sake of economy. To such proposal the meeting opposed strong objection and appointed a deputation to wait on the Chancellor to urge that the Regius Professor should be a physician who is representative of medicine in its evident sense, and that it would be detrimental to the best interests of medicine in Oxford for him to be converted into a professor of any one branch of medical science.

It is now announced that two of the natives brought over from the Congo supposed to have sleeping sickness were not affected with it. The one who died was on the voyage.

To the fund being raised by the Senate of the University of London to establish an Institute of Medical Science, the Dean of the Faculty (Mr. H. T. Butlin) has given £1,000. Each of the presidents of the two colleges of physicians and surgeons has given £100.

Messrs. W. H. Smith & Son have given £1,000 to the King's College Removal Fund. The Hon. W. F. D. Smith, M.P., presented the new site.

The death is announced, in his fifty-ninth year, of Mr. Knowsley-Thornton, consulting surgeon to the Samaritan Hospital, where his chief work as an ovariotomist was done. He had been president of both the Medical and Harveian Societies. His fifty additional cases of ovariotomy appeared in 1878 with notes of several other cases of abdominal section. He contributed articles on ovariotomy, hysterectomy, etc., to Heath's "Dictionary of Surgery" and Allbutt's "System of Medicine," and numerous papers on his special department of practice to the societies and journals. He retired in 1898, and was made a county magistrate (Cambridge).

OUR BERLIN LETTER.

(From Our Special Correspondent.)

INOCULATION OF SYPHILIS IN A CHIMPANZEE—CYTODIAGNOSIS OF TABES DORSALIS—PARAFFINE INJECTIONS AND PROTHESIS—UNIVERSITY APPOINTMENTS.

BERLIN, January 3, 1904.

THE researches of Drs. Roux and Metschnikoff at the Institut Pasteur in Paris regarding the inoculation of syphilis on anthropoid apes have been repeated in Berlin by Drs. Friedenthal and Lassar. The first read a paper at the Medical Society reporting that he had vaccinated a chimpanzee and a gibbon with liquid from a hard chancre, the inoculation being made according to the ordinary rule of such operations. A fortnight afterward the animals became very dull, and at the chimpanzee's foot a vesicle filled with a clear liquid was noticed. The gibbon's feet were still more affected and vesicles appeared on both the feet and hands. The axillary, inguinal, and popliteal knee-glands began to swell, but were apparently not painful or tender. A dermatologist was consulted as to these swollen glands, but no explanation could be given, so the diagnosis of syphilis was made, though there were no pathological marks of syphilis at the vaccinated spots. The post-mortem examination, however, showed that these vesicles were caused by the presence of some parasitic organisms. The microscopical examination made by Dr. von Hansemann demonstrated the presence of these microorganisms in the stratum mucosum and stratum papillosum. Therefore the diagnosis of syphilis was an incorrect one.

Dr. Lassar demonstrated, at the next meeting of the Medical Society, a chimpanzee which he had also vaccinated with the liquid of syphilis. The person from whom it was taken was a young man who had become infected through tattooing his arm. The chimpanzee was inoculated on the lips, on the mucous membrane above the fræulum linguæ, and above the eyebrows. The result of the experiment was that a fortnight later two ulcers appeared on the animal's forehead, which healed within six weeks. Swelling of the cervical glands took place and some maculæ were noticed on the palms of the hands, at the anus, and on the soles of the feet. Whether these lesions were syphilitic or not, Dr. Lassar was not prepared to say.

Dr. Frenkel communicated his researches on cytodiagnosis of tabes to the Neurological Society. He shares the view of Widal, Sicard, and Ravaut that in the early stages of tabes dorsalis the number of lymphocytes increases in the cerebrospinal fluid. In health no foreign cells are found in this fluid, yet in very early stages of tabes an enormous increase of the lymphocytes takes place. Dr. Frenkel thinks that this fact is of great importance in the differential diagnosis between tabes dorsalis progressive, paralysis, and cerebral syphilis.

Discussing Dr. Frenkel's report, Dr. Oppenheim thought that chronic alcoholism might also show an increase in the lymphocytes. Rothmann thought that syphilis in early stages might also give the same result, but Frenkel stated that in all cases of secondary and tertiary syphilis without an affection of the nervous system there were no lymphocytes to be found.

Eckstein has published a report on his experiments with paraffine injections. He prefers the hardened paraffine, whereas Gersuny of Vienna believes more in liquid paraffine. It will be remembered that several fatal cases of embolism have been observed after this operation; one case of special interest having been published in the MEDICAL RECORD of July 11, 1903. Eckstein thinks that danger lies only in the use of liquid paraffine. Gersuny has restricted the cases in which paraffine may be of any use to a very limited number, but Eckstein advises its use in cases of umbilical hernia and of harelip.

Even with adults he has seen good results with paraffine prothesis in umbilical hernia; and in cases of harelip he favors the injections into the posterior part of the palate, as he has seen several cases in which a great improvement in speech followed this procedure.

Privatdozent Dr. Fickes, at the Hygienic Institute of the University of Berlin, has been appointed as a professor to the institute.

Dr. Sultan, Privatdozent at the University of Giessen, has become head surgeon of the new Rixdorf Hospital near Berlin.

Dr. Bonhoeffer, professor of psychiatry at the University of Koenigsberg, has been appointed as a successor to Professor Kraepelin, who is now at the Munich University.

Dr. Heinz has been appointed to the Pharmaceutical Institute of Erlangen.

Dr. Gérra, professor at the University of Koenigsberg, has been appointed as a successor to the late Professor Gussenbaur of Vienna.

LETTER FROM THE PHILIPPINES,

(From Our Special Correspondent.)

CARE OF THE INSANE—REGISTRATION OF DEATHS—DANGEROUS BOTTLED WATERS—UNFOUNDED CHARGES AGAINST HEALTH INSPECTORS—STORY OF A SPRING—WAR AGAINST LOCUSTS.

MANILA, December 5, 1903.

A BOARD has been appointed by the commission to investigate into the question of caring for the insane throughout the islands and submitting plans and estimates therefor. Under the Spanish régime, a single asylum in Manila, with a capacity for two hundred and seventy insane, was the only institution for the care of these unfortunates throughout the islands. Ordinarily, the insane are cared for by friends or relatives, but those who are dangerous have been commonly incarcerated with prisoners in the provincial jails, where they received little attention and were placed under conditions far from conducive to recovery. The board now in charge of the matter is conducting a census of the insane throughout the islands, to secure definite information as to the number of such persons for whom hospital accommodations should be provided. It is conducting its work with the dual object of arranging for the necessary number of permanent institutions, to be modern in every respect, and at the same time to make temporary accommodations to relieve present necessities. The establishment of such temporary institutions in convents near Manila, is now being considered.

The sanitary authorities have established, in the office of the Board of Health for the Philippine Islands, a bureau for the registration of the deaths of all Americans or other foreigners occurring throughout the archipelago. Many requests for information concerning persons last heard from in the Philippine Islands are constantly being received from inquiring friends, business houses, and other sources, and in order to be able to give definite information as to whether such persons have or have not died, the deaths of all persons not natives of the Philippines, together with the essential facts of name, date, place, age, sex, and occupation, must hereafter be reported to the central office of the Board of Health in Manila. In order to render the records complete in this respect, the deaths of such persons which have occurred in the past since the American occupation must be reported. Since the deaths of all persons in the military service are reported on the military records, and any desired information can be readily secured therefrom, the Board of Health death records will not include the names of officers and soldiers of the United States Army.

Analysis of the soda waters and bottled drinks sold in Manila shows that many of them are of bad character and dangerous to health. The law requires that the water from which such drinks are made shall be boiled or distilled, but this law is easily evaded by the unscrupulous, who state that the water has been boiled before use, a statement hard to disprove. Many of the low-class vendors of drinks secure their water from the first available source, irrespective of its purity. A new law has recently been drafted under which all bottled waters, drinks, ice, etc., must be made only from distilled water or that from an approved source, and this will require manufacturers to install proper distilling outfits in their establishments or purchase pure water from some public distillery. By this means such establishments can be kept under better control. The law is very drastic, calling not only for the destruction of the impure drink or bottled water, but also for the publication of the name and address of the firm or establishment manufacturing the article, with a statement that such article has been condemned as unfit for use. Insanitary establishments are also to be closed until placed in good condition.

As a result of numerous complaints made by natives opposed to sanitary improvement, who charged that sanitary inspectors of the Board of Health abused their authority, a committee was appointed by the commission, to investigate this matter. This committee expressed itself as in readiness to consider any statements, provided these were substantiated by facts, but after the lapse of several months the required positive evidence has not been forthcoming and the health department has been entirely cleared in the matter. One native newspaper which had published a number of venomous attacks against the sanitary department, issued an appeal to the people to prefer charges, when it saw that its own position was not sustained, but without effect. The Filipino is somewhat inclined to brood general statements, and these are, of course, much exaggerated when passed from mouth to mouth, but he is not desirous of being put in a position where he may be called upon to give dates, names,and facts when he knows this to be impossible.

All this opposition to sanitary reform and resentment against sanitary control, has a most serious influence on the results accomplished by the health authorities. With an unwilling and unsympathetic population, whatever is accomplished, comes as a result of coercion. It is a well-known fact that the average native will take more time and pains to avoid the requirements of the Board of Health than would be necessary to comply with them, and this spirit is by no means confined to the less educated class. This is not hard to understand. The natives, as a whole, are uncleanly in their surroundings and mode of life, and are imbued with superstition and fatalism. To these, modern sanitary rules come in conflict with racial custom, personal preference and religious teaching, and naturally the visit of the sanitary inspector is regarded with resentment and disquietude. The struggle against the combination of filth, disease, superstition, and idleness will be long and fierce, and victory will finally be won through the education of the younger generation away from the sanitary standards of the fathers.

The report of the Commissioner of Public Health for September gives an interesting incident showing the difficulties under which sanitary work is done among a peopl · whose credulity and superstition as yet frequently outweigh their faith in sanitary measures. During the first seven days of September and for some time previously, the ases of cholera had been scattering and had averaged but little more than one a day—such cases as occurred being largely limited to those who persisted in using the contaminated water of the river and esteros. On September 7 a spring of fresh water was found discharging on the Tondo water front into the salt waters of the bay, below low-tide level, and near the mouth of a sewer. This spring was at once made much of by the superstitious and various stories told of its discovery. The one most commonly believed was that an image of the infant Christ was seen floating in the waters of the bay. On the effort being made to pick it up, the image rose into the air and disappeared, while a stream of fresh water bubbled up in the place where it had been floating. The story was rapidly spread and hundreds came to drink and bathe in the miraculous waters, to which were attributed marvelous curative powers. Because of the *quasi*-religious quality with which the spring was endowed and pending examination of the water, the spring was not at once quarantined. Examination showed the water to have the qualities of sewage, and at the same time the cases of cholera through the city greatly increased. Investigation showed that many of those attacked by cholera drank of the waters of the spring, and cases occurred in sick persons to whom the water was brought by well-meaning friends. The spring was closed on September 13. During the seven days after it was discovered, 150 cases of cholera developed; in the week after it was closed the cases fell to 79, and in the next week to 64, after which there was a steady decrease to normal as the new centers of infection through the city were eradicated. It took, however, about six weeks to destroy the infection so that only a case or so occurred weekly. The outbreak was largely limited to the less intelligent classes who had flocked to the spring. The educated Filipinos largely escaped, and such cases as did occur among them and among whites were derived from secondarily infected foci of the disease. There were but four cases among Americans in a total of 290, and of these all were apparently traceable to a single secondarily infected point. Not less than 225 cases of cholera occurred as the result of the appearance of the spring and the superstition of the lower classes. The source of the spring was apparently a break in the sewer discharging near it at a higher level.

Work on the much-needed leper colony on Kulion Island has been delayed by the inability to secure sufficient native labor, and there has also been some trouble over the water supply. The work will now be let out to

private contractors, and probably much of it will be done by the Chinese or Japanese, large numbers of the latter now coming to the islands to perform the labor which there seems to be no possibility of securing Filipinos to do. There is some intention of locating a large penitentiary and reformatory on Kulion, and also a large asylum for the insane, as the island is plenty large enough for these several purposes.

The authorities have finally begun a systematic warfare against locusts, which are a curse to agricultural interests in many provinces. A law has been passed by which this matter is placed under a board established for each province, which is given power to call out every able-bodied man to assist in killing off these insects. Such persons are supported by insular funds while so engaged, and persons not complying with the orders of the board are heavily fined, and the money thus received is turned into a fund to be used for paying bounties on locusts killed by those who respond to the call. Special effort is to be made to destroy the locusts before they develop to the flying stage, as they can be more readily despatched by concerted effort. The hatching grounds are to be located, and as soon as the young locusts appear they are to be driven into deep trenches by means of portable fences, and covered up with earth or destroyed by fire. So far, this procedure has been very effective, though some of the natives are not anxious to see the locusts destroyed, but prefer to have them live, to be later used as food.

SHALL THE CONSULTANT DIVIDE FEES WITH THE GENERAL PRACTITIONER?

To the Editor of the Medical Record:

Sir: The general practitioner is still the power in the profession. The good all-around-man still dominates the family. He is called upon to decide whom to consult in troubles with eyes and ears, in surgery and internal medicine. He usually directs the patient to good men, and thereby proves that he has the interest of his client at heart. The broad-minded practitioner, therefore, is the man of the hour. His deference to the consultant, when he calls him for advice, and gets the benefit of modern treatment, medical or surgical, is usually repaid by having the consultant strengthen him with the family. The consultant, by reason of his specialty, does not compete with his brother practitioner. He has practically isolated himself by becoming a specialist. Having done so, his fees are larger comparatively, but the number of his patients is smaller. An inquiry into the relative amount of money earned by the general practitioner compared with that by the specialist usually shows that the general practitioner fares very much better, financially, on the whole, than his distinguished confrère. The question therefore arises, shall the general practitioner be entitled to any share of the consultant's fee? It is said that there is a growing tendency to request the consultant to share his fee and wrongly so with his brother practitioner. It is even hinted that certain physicians demand a portion of the consultant's fee before the consultant has seen the patient. One physician, it is said, recently refused to meet a general practitioner in consultation because he was requested to divide the paltry fee of $10 in two.

It seems to me that others must have heard of this condition existing in the profession. Would it not be well to obtain some general opinion on this vital subject?

Specialist.

January 23, 1904.

The Fontanelle or Issue as a Therapeutic Measure in Tuberculosis.—Blöte says that the beneficial results formerly observed under the application of an "issue" or superficial suppuration, artificially produced and maintained by introducing some foreign body like a pea into a small incision finds its explanation in the principles of the modern serum therapy. By the constant presence of suppurative organisms at the site of the issue a steady supply of antitoxin is being formed, which assists the body in combating some other more virulent and deeply-seated infection. The measure itself is perfectly harmless, and the issue can be healed in a week if its further presence seems undesirable. In pulmonary tuberculosis the great danger is that of mixed infection of tuberculous areas with pus producers, and it is readily conceivable that this old-fashioned procedure might advantageously be employed to-day to prevent destruction of lung tissue and cavity formation. —*Zeitschrift für Tuberkulose und Heilstättenwesen*, Vol. V, No. 2.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Jan. 21, 1904.

The Prevailing Conception of Degeneracy and Degenerates, with a Plea for Introducing the Supplementary Terms Deviation and Deviate.—G. L. Walton declares that degeneracy has come to include, medically speaking, every form of constitutional variation, however innocuous, from the average normal. It is not logical to conclude that every deviation is degenerative because undoubted degenerates show many such signs. These stigmata range all the way from flocks on the iris to insanity and idiocy. It seems that they are neither more nor less than deviations from the average normal type. Not every physical peculiarity is truly degenerate; for example, while albinism may be justly regarded as degenerative, in that it implies absence of a useful constituent in the organism, a mere difference in color of the eyes is not necessarily degenerate, though it must be classed so under the present method. The term deviation may cover all variations from the average normal, whether above or below, or at the same level, in the intellectual, physical, moral, or other scale.

Clinical Lecture on Epithelioma at Massachusetts General Hospital.—J. Collins Warren calls attention to the two principal varieties of epithelioma. One is almost a malign growth and the other approaches more nearly to cancer in a clinical sense. In cancers of the skin two varieties must be recognized: First, a very superficial type known as the rodent ulcer, a small-celled epithelial cancer, and second a polymorphous-celled type characterized by larger cells, among which the characteristic nests of cells occur. The type of the former of these two varieties is the rodent ulcer of the face; types of the latter form are cancers of the lip; of the back of the hand, and of the penis. The writer goes on to describe the history of rodent ulcer, so well known to the clinician. It has an early stage when the growth is very slow, then suddenly it becomes more rapid. It begins with roughness of the surface, with a tendency to scab formation. An ulcer is finally formed. The diseased process sometimes goes on for forty years or more. Examination shows no enlargement of the lymphatic glands. This is a very characteristic feature of the disease, which makes the prognosis encouraging. The more malignant type, such as cancer of the lip, is generally associated with enlarged glands. It is now pretty generally admitted that *x*-ray therapy has a favorable influence upon very superficial carcinomata, but that the more deeply seated growths are not affected by it. It seems hardly justifiable to lose valuable time in treating a cancer of the lip, or any of its allied forms elsewhere on the body, in their early stages with *x*-rays. Prompt extirpation is indicated. In the earliest stages of rodent ulcer the removal is so easily and painlessly accomplished by the aid of subcutaneous injections of cocaine and the knife, that is is hardly necessary to consider the influence of the rays upon them. The same is true of growths ranging in size up to that of a quarter of a dollar, unless their removal would result in considerable deformity. The writer closes with a plea for more radical operations for cancer of the lip than are usually performed. He believes that the practice of incomplete "ambulatory" operations, with the aid of cocaine anæsthesia, cannot be too strongly condemned. The *x*-ray therapeutist should make himself thoroughly familiar with the more advanced and malignant phases of rodent ulcer if he wishes to make an intelligent selection of cases for treatment.

Journal of the American Medical Association, Jan. 23, 1904.

Relation of Epilepsy to Chronic Gastrointestinal Disease.—The modern views on this topic are reviewed by G. W. McCaskey, who gives the history of the case of a woman aged twenty-seven years. Seizures had been recurring about every three or four weeks for nine years. The patient was somewhat under the average power of mental and physical endurance. Examination revealed chronic gastritis and colitis and suitable treatment was instituted, but there was no substantial improvement in either the gastrointestinal disease or the epilepsy during the time that the patient was under observation—which was perhaps two or three months. The putrefactive processes of the intestinal tract seemed entirely beyond control by either diet or medication combined with suitable local treatment, and the patient finally passed from observation unimproved. A second case was that of a boy of fifteen years presenting a history of irregular nocturnal attacks of *grand mal* closely associated with exacerbations of a chronic disease of the stomach. In this case an apparent cure of the epilepsy followed a comparatively brief treatment and the patient was remaining well, three years later.

Perforating Wound of Both Cerebral Hemispheres.—The case of W. S. Lindsay was that of a young man aged nineteen years who had shot himself in the right temple,

five minutes before being seen. Bleeding was not severe, mentality seemed normal, and the special senses were not disturbed and movements of the various bodily muscles were coordinated. Examination at the hospital an hour later showed what was in effect a perforating wound of the brain, for the bullet, which was from a 32-caliber revolver, was found outside the skull on the left side, nearly opposite the point of entrance, which was one inch and a half superior and one inch and a half anterior to the meatus auditorius on the right side. The patient made an uneventful recovery, at no time showing signs of impairment of brain function, leaving the hospital on the fifteenth day seemingly as well as ever. Four months after the injury, the author examined the patient and found that on leaving the hospital the patient began the study of telegraphy, that he was now taking twenty-five words per minute, and expected to take a position with a railroad company. Examination for symptoms of sequelæ was entirely barren of results, except that there was found an unusual redness of the face. This had been a characteristic before the wound, and was simply exaggerated afterward. There had been no head pains, no flushing of the face, no defect of any sense and no interference with ideation. [In the discussion following the reading of the paper the criticism was made that one would be handicapped in pronouncing on the case as to the course of the bullet unless the exact track had been verified by autopsy, and that with such a rapidly moving body as a bullet it would be impossible to estimate how much of the injury was due to the passing of the bullet, and how much to the resulting injury and hemorrhage.]

Medical News, January 23, 1904.

Prevention of the Spread of Ringworm.—F. H. Beadles states that it has long been undisputed that the various lesions described under the title of ringworm are due to the presence of a vegetable parasite in the epidermis, hair follicles, hair, or nails. Many valuable additions have been made of late years to our knowledge of ringworm fungi. The writer points out some of the mediums of transmission. Among these may be mentioned some of the lower animals, as the dog, cat, bird, horse, cow, mouse, sheep, and many others. The nearer a fungus is to its animal origin the more rapid its growth. It loses its vitality by human transmission. Animals are not entirely responsible for the transmission of this disease. There are excellent opportunities for its diffusion in barber shops, bath houses, asylums, day nurseries, and public schools. The disease is not conveyed by the razor, but by the barber's hands, or by towels; but most often by the lathering brush. The child often catches the disease in having his hair cut by the barber. The patient under treatment should be required to sleep alone and use separate towels, combs and brushes, these articles being frequently sterilized to prevent reinfection. All domestic animals or pets which are found to be mangy should be either destroyed or isolated until, by proper care, they can be rendered incapable of the transmission of the fungus.

The Pathology and Treatment of Osteoarthritis.—Edward M. Merrins considers all the conditions in which there occur arthritic or osseous lesions more or less resembling those found in osteoarthritis. He classifies them under three heads: Infective or toxic; nutritional; traumatic. The characteristic lesions of osteoarthritis occur during the course of many infective or toxic diseases, as locomotor ataxia, tuberculosis, leprosy, syphilis, gonorrhœa, rheumatism, and gout. They are found also in various other affections, such as chronic gastrointestinal anti-intoxication and uterine disease. After repeated attacks of acute or subacute articular rheumatism, lipping occurs or osteophytes are formed, the disease thus merging into osteoarthritis. Osteophytic formation and the destruction of cartilage may result from repeated attacks of gout in a joint. In cases in which rheumatoid arthritis does not appear until middle life is reached, the characteristic osteophytes are often found in the affected joints. In certain hypertrophic affections of the bones and joints, there is imperfect or perverted nutrition. Any abnormality in the internal secretion of various glands may cause overgrowth of tissue. In acromegaly and in osteomalacia, the changes in the bones are well known. A large proportion of the cases of monarticular osteoarthritis are due directly or indirectly to some form of traumatism. The great majority of traumatic cases of osteoarthritis are found among elderly people. Evidences of osteoarthritis have been found in human remains, almost prehistoric, and in the bones of animals now extinct. Treatment is both general and local. The medical treatment is that which is appropriate for the primary condition. The source of the systemic affection must be removed and the toxins eliminated from the system. Local treatment must be very carefully applied. As soon as possible after all acute inflammation has subsided, the joints should be given baths of superheated dry air, followed by gentle passive movements of the joint and massage of the neighboring muscles, gradually increasing the range of motion. Severe pain and inflammation should never be caused. In the early stages of the disease, rest and alleviation of pain are necessary. The aim of all treatment must be to check the morbid process, keep the patient comfortable, and secure, as far as possible, freedom of movement in the joints.

New York Medical Journal, January 23, 1904.

Sterile Water Anæsthesia in the Office Treatment of Rectal Diseases.—From an experience of one hundred and fifty cases S. G. Gant is convinced that sterile water fulfils all the requirements of a local anæsthetic in rectal affections calling for operation. All the common lesions have been thus operated on without any unpleasant effects. The temperature of the water is immaterial. Pain and bleeding are less than when drugs are used. The anæsthesia is complete and instantly follows the injection, provided the latter has lightly distended the tissues to be attacked. There is no danger to any internal organ or function. The only requirements are a syringe, needle, and boiled water. The author states that the radical treatment of hemorrhoids can be so easily carried out under this method in the physician's office, with so little danger and inconvenience to the patient, that it should relegate to oblivion the much-vaunted injection treatment, which is so dangerous and uncertain.

Puerperal Sepsis and Its Treatment by Iodine.—W. R. Pryor combats the obstetrical teaching that in most cases of puerperal sepsis the infection remains localized in the uterus. His own experience has forced him to conclude that in streptococcic septic puerperal fever, pelvic lymphangitis and phlebitis are early complications. In a given case he seeks to isolate the infected uterus between masses of iodoform gauze (details for the preparation of which are given) and by local and systemic iodine to destroy the cocci. He irrigates the uterus and packs it full of gauze, 10 per cent. strength. The posterior cul-de-sac is then opened by a broad incision, adhesions separated, the uterus lifted and the pelvis packed full of gauze, 5 per cent From ten to fifteen gauze strips one yard long and eight inches wide are thus used. Cardiac stimulants are given as indicated and a self-retaining catheter is inserted. The urine is tested from time to time for iodine. From an experience of thirty-seven personal cases and sixteen in the practice of other operators, Pryor is convinced that this procedure offers much better results than does hysterectomy. Of the fifty-three cases enumerated, a previous curetting had been done in ten, and of these, three died. In forty-three cases not previously operated on, but one died.

American Medicine, January 23, 1904.

The Modern Treatment of Wounds.—Walter Lathrop states that he has had under his care during the past four years nearly two thousand wounds of various kinds. The majority of wounds which railway surgeons are called upon to treat are of the lacerated variety. In treating this type of wound, hemorrhage should be checked, and the wound and surrounding parts then carefully cleansed. If the injury is severe, the patient should be etherized, so that the cleaning of the wound may be thorough. The writer prefers formaldehyde soap, 10 per cent., to begin with, followed by mercuric chloride solution and sterile water. The skin is trimmed where it is necessary, and the wound converted, as nearly as possible, into an incised one. Severed tendons are united, and the injured member dressed with sterilized gauze and cotton. A dusting powder may be used if advisable. Drainage is sometimes necessary. The writer then uses sterile or iodoform (5 per cent.) gauze. If the wound have clean-cut edges, the aseptic procedure should be thorough in order that primary union may take place. The subject of infection is most important. The writer believes that the injudicious use of poultices is the cause of more cases of infected wounds, abscesses, diffuse cellulitis, and septicæmia than any other agent except direct infection. The common poultice is a hot-bed for bacteria. The one great agent in combating infection is carbolic acid. In cases seen late in which the septic process has invaded the system, the use of antistreptococcus serum is very valuable. In gunshot wounds of the extremities the Röntgen ray is a great help in locating the bullet, and makes its removal easy.

Physical Overexertion, and Its Effects on Health.—John Knott emphasizes the fact that exercise, in order to do good, must be indulged in with moderation. In analyzing the effects of exercise, the writer first touches upon the muscles. In an active muscle, nutritive changes take place far more rapidly, and on a larger scale, than in a resting one. The waste products are carried off in larger quantity, and new materials are absorbed with greater rapidity. Again, muscle forms so large a proportion of the

mass of the body that it is known as the great furnace of the animal economy—about four-fifths of the total heat of the system being evolved within it, It is most important to maintain a healthy functional activity of the muscular system. With the increase of the muscular action the amount of waste products is also increased. Up to a certain point, the system is able to eliminate this waste, but in over-exertion a point is reached beyond which the effete products begin to accumulate in the circulation and in the tissues. Fatigue then becomes manifest. When muscular fatigue is carried to excess, the healthy nutrition of the other organs and tissues can no longer be maintained. This condition has a special effect upon the nerve centers. When the nutrition of the latter becomes deranged, the nutritional changes and functional capacities of the whole system are disturbed. The writer then touches upon the phenomena of excessive muscular exertion, which take place in running. "The brain is overcome by a kind of drunkenness." The writer believes that the "fever of over-exertion" is due to the poisoning of the nerve centers by the muscular waste products. The heat-regulating centers lose their governing powers and the body wastes with slow fever. There are various local affections which are likely to be produced by excessive exercise, such as hypertrophy and dilatation of the heart, aneurysm, and varicose veins. It is necessary for even those who have been blessed with an unusual physique to remember that the overuse of the body may lead to a sudden and permanent breakdown of health.

Deutsche medizinische Wochenschrift, January 1, 1904.

Is Appendicitis More Frequent Now than Formerly?—Villaret has found, from the statistics of the German Army, that while in the year 1873 the percentage of cases of appendicitis was only .52 per cent., in 1900 it was 1.73 per cent. That this increase is only apparent, however, is shown by the fact that peritonitis, liver diseases, and stomach diseases have all fallen off greatly, so that while in 1873 the total morbidity from these three conditions plus appendicitis was 4.79 per cent., in 1900 the corresponding figure was only 2.66 per cent. It is therefore clear that the greater number of cases of appendicitis encountered at present is due only to more accurate diagnosis.

The Relations of Anthrax Bacilli to the Endothelial Cells of Mice and Guinea-pigs.—Behring and Much found that by using a special stain of eosin, methylene blue, and glycerin, peculiar staining reactions were produced in the endothelial cells of experiment animals infected with cultures of anthrax bacilli. By careful adjustment of the virulence of the cultures employed, it was possible to protract or shorten the course of the disease and produce staining pictures of different characters. The bodies of the endothelial cells of normal animals are stained pale blue by this method, but after infection with slightly virulent cultures of anthrax bacilli, particularly if the course of the disease has been protracted, the blue is replaced by a pink color, which is termed oxyphilia. From ten to many hundred times more bacilli are found in the endothelial cells of the heart and vessels than in the blood, and the organisms appear to invade the sub-endothelial lymph spaces also. Similar observations were made on the peritoneal endothelium. The authors believe that the oxyphilia of the endothelial cells represents a degenerative change produced by the action of the bacteria, and that these cells finally undergo colloidal disintegration and set free agglutinins specific for the organisms in question. The antibodies for the toxin of anthrax bacilli originate in the endothelial cells, and are brought into contact with the bacterial poison through the colloidal solution of the antibodies in the intravascular fluids and intracellular tissue juices.

The Treatment of Post-partum Hemorrhage.—Fritsch says that post-partum hemorrhage due to atony is usually the result of improper management of the third stage, *i. e.* under haste to express the placenta or premature massage of the fundus. This causes partial separation of the placenta while the uterus is still unable to contract firmly on account of its contents. Packing the uterus requires time and experience, and considerable blood is lost in executing it. The author's method consists in seizing the uterus with both hands and expelling all coagula and then lifting it upward and forward so as to anteflect it forcibly over the symphysis. The abdominal wall is then pushed deeply into the pelvis behind the uterus and the depression so formed filled with folded towels, cloths, gauze, or anything available. This mass is secured by several turns of a bandage very firmly applied, and one or two more turns are placed over the fundus so as to compress it against the posterior pad. In this way the uterine cavity is obliterated so that no further bleeding can occur and no asepsis or intrauterine after-treatment is required. The apparatus does not give pain and is removed at the end of eight to twelve hours. Suturing lacerations to check hemorrhage is poor practice, because it is not possible to carry the needle deep enough without risk of injury to the ureter, and tamponnade is not effective if a large vessel is torn across. The author has found the following the best plan: Remove the placenta and press the uterus deep into the pelvis with the right hand. Catch the labia majora with the fingers of the left hand and push the vulva upward as if to meet the uterus. Forcible pressure in this way obliterates all dead space, and at the end of one-half to three-quarters of an hour the upper hand may be replaced by a sand-bag or other suitable heavy object.

Berliner klinische Wochenschrift, January 4, 1904.

Actinomycosis or Osteomyelitis of the Femur?—Von Bergmann says that recent studies on the nature of the actinomycosis fungus have shown that it merits greater consideration than has been accorded it in the past, and that it may occasion difficulties in diagnosis. It has been established that in addition to the modes of entry into the human body of the fungus formerly recognized, viz., the mouth and pharynx, the respiratory tract and the alimentary canal, a fourth must be added, through the skin. Köhler has described a case in which the tibia was attacked and seriously damaged by an actinomycotic infection which could only have occurred through the skin, and the author reports a case of his own in which actinomycosis of the soft parts closely simulated osteomyelitis of the femur. The patient, a man of twenty-nine, five years previously had been kicked in the knee by a horse, and though the wound of the skin so produced had healed under suitable treatment, a painful swelling of the region followed and finally completely incapacitated him. On coming under observation the picture presented in many ways resembled an osteomyelitis, but a number of features, such as the extreme chronicity of the case and the absence of temperature, were against this diagnosis, and on incision widespread actinomycotic invasion of the soft parts was found. The femur was intact, and after five months of treatment, consisting of repeated curettages of the areas involved, recovery ensued.

French and Italian Journals.

Experiments on Strangulation of the Intestine without Perforation.—Giuseppe del Conte reports eight experiments showing that it is not difficult to cause death by intestinal obstruction and without perforation or gangrene of the intestine. In these cases the injury to the intestinal muscles is most important, as it can oppose an insurmountable barrier. The animal never dies of septicæmia in this condition, but death comes from autointoxication.—*Giornale Internazionale delle Scienze Mediche*, November, 1903.

Malignant Degeneration of the Cervix after Hysterectomy in Fibroma.—Richelot says that he prefers total hysterectomy to any less radical operation, unless there is a serious counterindication. He prefers hysterectomy to myomectomy in all cases which are no longer young and when the uterus is not worth saving. He says that the fibrous degeneration has not deserved its benign reputation, and these tumors should be kept under observation from the beginning, because operation is indicated as soon as there is any sign of change. Often when indications for operation are disregarded, the patient succumbs to phlebitis or visceral complications. Carcinomatous degeneration is much commoner than sarcomatous.—*Annales de Gynécologie et d'Obstetrique*, December, 1903.

The General Treatment of Dermatoses.—Busscires teaches that certain articles of food, as strawberries, shellfish, and fish, may cause urticaria, in certain individual cases and if long continued, eczema. In other subjects with more sensitive idiosyncrasies, these disorders may follow ingestion of veal, eggs, etc. Some kinds of foods increase the pruritus of dermatitis or produce it *de novo*. Above all, alcohol is of importance. Psoriasis, usually indolent, becomes itching in alcoholics. Also coffee, pastry, crawfish, paté de foie gras, game, etc., act in a similar complex way. It is noted that certain dermatoses are produced or aggravated by a defective diet, rather because it is too abundant than because it is too limited, especially so when the general hygiene is also defective. There is no special diet for dermatoses, but each patient must have a special régime, which is partly determined by the dermatosis and partly by the other morbid manifestations, exhibiting or expected, hereditary or personal. Alimentation is only a part of the régime; it also includes general hygiene, which demands a balance between the ingesta and the activity of the individual. Overeating is common in adults and more so in children. An old author says that what one eats can be divided into thirds, one part for the needs of the body, one for gluttony, and one for the soil for future diseases. Besides other precautions, sufficient exercise is necessary. Some eczemas can be cured

with a bicycle. Fresh air is also necessary. Walking, riding, and boating give results which gymnastics alone do not accomplish. Neurasthenia, moral depression, and mental fatigue are often the causes of nervous dermatoses. These require a change of air and scene.—*Journal de Médecine de Bordeaux*, No. 1, 1904.

The Chronic Inflammations of the Suprarenal Gland of Infectious Origin and Chronic Suprarenal Insufficiency.—In the case reported by Emile Sargent the patient had asthenia, emaciation, anæmia, vomiting, abdominal pains, tachycardia, high arterial tension, and tendency to elevation of temperature, and to collapse and fainting—all of which compose the usual picture of chronic suprarenal insufficiency. In addition, in this case there were tetanoid contractions of the masseter muscles before death. Muscular exhaustion consequent on the suppression of the capsular function is a new element in diagnosis. Very slight intercurrent infections, as a sore throat, may have a grave prognosis in these cases, even a rapidly fatal ending. The author emphasizes the point that toxic infectious diseases may leave extensive changes in the suprarenal gland as sequelæ, comparable to chronic nephritis after scarlatina and giving the syndrome of the affection under consideration—that is, a simple insufficiency with melanoderma. The author had previously reported a case of sudden death from acute suprarenalitis in pneumonia. It is probable that there are many cases of acute suprarenalitis which are not severe enough to leave permanent effects. In the author s case there was cirrhosis of the gland. The history of the case explains some doubtful points in the pathology of the capsule and also of Addison's disease. The integrity of the nervous plexuses in these cases of suprarenalitis is undeniable, and the lesion is found only in the gland. The symptoms noted are dependent upon the suprarenal secretion, but the case is different with the melanoderma. The clinical history of toxic infectious suprarenalitis is sufficient to establish a simple insufficiency in contradistinction to Addison's disease, in which irritation of the neighborhood of the sympathetic plexuses is combined with the destructive lesion of the capsule; thus accounting for the melanoderma associated with the suprarenal insufficiency.—*Archives Générales de Médecine*, No. 1, 1904.

The American Journal of the Medical Sciences, Dec., 1903.

A Case of the Epiphenomena of Diphtheria Antitoxin.—James P. Marsh reports this interesting case. He injected into the subcutaneous tissue of the back of a patient suffering with diphtheria, the contents of a bottle of diphtheria antitoxin. The bottle contained 1,500 units of the antitoxin. The patient within a few minutes was seized with severe symptoms. She became very much cyanosed and semicomatose. She was numb all over her body, and she could not see anything in the room. A severe itching, stinging rash came out all over her body. It took about thirty-six hours for the rash to disappear entirely. The patient's convalescence was rapid and uneventful. The writer believes that this case came very near being fatal. The symptoms, he thinks, were not due to the antitoxin, *per se*, but to an idiosyncrasy on the part of this patient to contact with a horse or anything derived from that animal. The patient gave the history of always being affected by uncontrollable sneezing attacks whenever she came neat to a horse.

A Contribution to the Surgery of Cerebral Tumors.—George Woolsey presents an instructive paper including a table of 101 cases of cerebral tumors. He emphasizes the following conclusions: (1) The sphere of operation for cerebral tumors may be and has been extended to those parts of the cortex where tumors are accessible and localizable, *i.e.* to the prefontal, parietal, and occipital regions, in addition to the motor area. (2) The prognosis, both immediate and remote, is as good or even better than in operations for malignant growths in some other locations. (3) This prognosis has improved with the improvements in localization and operative technique, and with the limitation of the radical operation to cases accurately localized. (4) The palliative operation is strongly indicated to relieve symptoms where localization cannot be accurate'y made or the tumor cannot be removed. The exploratory operation is contraindicated. (5) Practically all circumscribed growths of moderate size are suitable for operation. (6) The osteoplastic method should be employed and the most rapid and perfect technique adopted which the circumstances allow.

Clinical Lecture on the Symptomatology and Treatment of Trifacial Neuralgia.—Charles H. Frazier in discussing the etiology of this affection, states that in every case, the fundamental cause lies in some structural change, either central, *i.e.* in the Gasserian ganglion, or peripheral, in one of its divisions. The symptoms of any one case will depend upon whether the ganglion or one or all of its divisions are affected. The pain is spontaneous and paroxysmal. Pain may nearly always be elicited by pressure over the so-called "tender points." In summing up the treatment of trifacial neuralgia, the writer believes that in all incipient cases the predisposing cause should be removed. Strychnine should be administered hypodermically in heroic doses under proper precautions. In cases that do not respond to this mode of treatment, where the pain is referred to but one branch, the peripheral operation is to be recommended, even though the operation may have to be repeated. It will afford relief, at least temporarily in every case, and in some cases permanently. When the peripheral operation has failed to afford but temporary relief, even though it may have been properly executed and repeatedly performed, or when from the outset the pain is referred to two or more branches, recourse should be had at once to an intracranial operation, either division of the sensory root, or, in certain selected cases, division of the second and third divisions, with interposition of a foreign substance to prevent reunion.

Tumors of the Sigmoid Flexure.—C. A Ewald gives a general review of tumors of this region. Fecal accumulations are the most frequent, and present but little difficulty in diagnosis. These tumors are comparatively soft, and they not only occupy the descending colon, but also the rectum. Of the solid tumors, the most frequent are the carcinomata of the sigmoid. The constant loss of weight, for which there is no known cause, is most suspicious in such cases. The appetite remains good. There is no vomiting, and no local pain. In one group of cases, the neoplasm grows into the lumen of the intestine, drawing the outer wall into it. It is hardly possible to palpate this growth, as there is no thickening. Such growths for a long time may lead to but slight symptoms or no symptoms at all. Suddenly there may occur an obstinate constipation. Such attacks may repeatedly occur until finally cathartics are of no use. The writer calls attention to those cases of highly situated hemorrhoids which are the source of continuous bleedings. These must be differentiated from malignant tumors. Finally, attention is called to the condition of autointestinal intoxication as a result of marked constipation of long standing. Palpation of the abdomen reveals several hard, fecal masses. After the intestinal tract is cleared there is a complete return to normal condition.

The Anatomical Basis of the Argyll-Robertson Pupil.—Henry M. Thomas discusses Argyll-Robertson's explanation of the symptom which bears his name, adding that the solution of this question is still to be found. The writer gives certain conclusions which he believes to be the best substantiated view: The sphincter and dilator muscles of the iris are composed of smooth muscle fibers, and are each controlled by sympathetic nerve fibers. As is true of the sympathetic nervous system in general, the path from the central nervous system to the periphery is made up of two sets of nerve fibers—the so-called pre-ganglionic and the post-ganglionic fibers. The pre-ganglionic fibers, which control the sphincter muscles of the iris, arise from a definite group of cells in the anterior part of the nucleus of the third nerve, and run to the ciliary ganglion. From this ganglion the post-ganglionic fibers arise and are distributed through the short ciliary nerve to the sphincter muscle. The path controlling the dilator muscle is a longer and more complex one. Its pre-ganglionic fibers arise from cells in the spinal cord, which are probably situated in the lateral horns, about the level of the junction of its thoracic and cervical portion. The fibers leave the cord mostly by the first thoracic nerve and run in the cervical sympathetic to the superior cervical ganglion. From this structure post-ganglionic fibers arise, which, after a somewhat circuitous route, reach the eye and the dilator muscle of the iris through the long ciliary nerves. The writer cites the views of various authorities on this subject, among which that of Bernheimer is simple and direct. He believes that the reflex arc upon which the contraction of the pupil to light depends is of the simplest nature. The apparent line is made up of the pupillary reflex fibers, which arise in the retina, partly decussate in the chiasm, and run directly to the sphincter center of the third nucleus, the center on each side receiving fibers from both optic tracts, and being virtually connected with each other. The efferent limb is composed of fibers which arise in the sphincter center and run directly to the sphincter muscle of the iris without making connection with the ciliary ganglion or elsewhere. The writer declares that the data which wehave at present are too incomplete and conflicting to allow any of the present views to be accepted as final. However, if these fibers do not end as Bernheimer believes, we do not know how they end. Marina insists upon the importance of the ciliary ganglion, although he admits the presence of other reflex centers for light. Knowledge of the sympathetic system is too incomplete to allow us to formulate any clear idea of how the ciliary ganglion could act as a reflex light center.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-eighth Annual Meeting, Held in Albany, N. Y., January 26, 27, and 28, 1904.

FIRST DAY—TUESDAY, JANUARY 26.

THE meeting was called to order by the President, Dr. Algernon T. Bristow of Brooklyn, in the Council Chamber of the City Hall, Albany, at 10.15 A.M., and the session was opened with prayer by the Rev. Dr. Whittaker.

President's Inaugural Address.—Dr. A. T. BRISTOW presented this address. He favored the continuance of the semi-annual scientific meetings. At present the total active membership of the State Society was 1,135, made up of 673 delegates and 462 members. The total membership of all the county societies was 5,680, and if the State Society reorganized on the plan now under consideration, the membership would be 5,700.

Regarding recent epidemics of typhoid fever, the speaker said that it was of little use for our State to make laws against the pollution of running streams unless similar laws in other States protected each State from contamination arising beyond its borders. A secretary of public health was as much a necessity as a secretary of commerce or of agriculture. Defects in the laws regarding the sale of dangerous drugs, and the restrictions on the practice of medicine were pointed out and commented upon. The control of quackery could never be really effective, the speaker said, until all distinctive sectarian titles were no longer recognized by the State, and were generally discarded. It should be the sincere hope of all that these titles would soon be merged into the ancient and honorable title of "Doctor of Medicine."

In conclusion, the president said that after twenty-two years of strife, heart-burning, recrimination, and misunderstanding, it was at last possible, by a stroke of the pen, to have peace, and it was for the society to decide whether it would have this or not.

Report of the Joint Committee of Conference.—The report of this committee was read read by Dr. HENRY L. ELSNER. The outline of the proposed plan of consolidation of the two State medical organizations has already been published (see MEDICAL RECORD, January, 16, p. 103). The report of the expert accountants on the financial condition of the two contracting parties showed a balance on hand in the treasury of the State Society of $2,744.25, and in the treasury of the State Association of $4,531.54. This last amount does not include the library, the original cost of which is estimated at $35,000.

During the reading of the report of this committee, which included the proposed constitution and by-laws of the united and reorganized society, there were over 150 persons present.

Dr. A. JACOBI, Chairman of the Joint Committee of Conference, also made an address. He emphasized the fact that perfect harmony had existed throughout all the many and trying deliberations of the committee. Special thanks were due to Dr. Henry L. Elsner and to Dr. W. R. Townsend of the committee, and to the president of the society, Dr. A. T. Bristow. He exhorted all the county societies to exercise patience, good sense, and patriotism, and to heed the urgent call of the hour for union of the profession of this great State.

Dr. Jacobi then moved the adoption of the following resolutions:

"*Resolved*, That the report of the Joint Committee of Conference be accepted, and that the proposed agreement for the consolidation of The Medical Society of the State of New York and The New York State Medical Association be, and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name, and on behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereto; and be it further

"*Resolved*, That the committee of the society, heretofore appointed for the purpose of bringing about the consolidation, be, and is hereby continued, as such committee with full power and authority to do whatever may be necessary to carry the agreement into effect."

Speeches were made by Dr. D. B. St. John Roosa of New York, Dr. William Warren Potter of Buffalo, Dr. Willis G. Macdonald of Albany, and Dr. Roswell Park of Buffalo, heartily seconding Dr. Jacobi's motion, and the resolutions were carried unanimously amid prolonged and enthusiastic applause. The report was ordered printed and distributed to every physician in the State.

Report of the Committee on Hygiene.—Dr. JOHN L. HEFFRON of Syracuse presented this report. In speaking of the ravages of typhoid fever, he said that every village, city, and house sewering into public waters should be compelled to purify such sewage before it is allowed to enter such waters. Even more important, however, in his opinion, was the proper disinfection of typhoid discharges. The prevalent idea that frost killed typhoid germs, should be vigorously and intelligently combated. The society should give its support to a bill, now before the Legislature, forbidding the sale of blank cartridges to minors.

State Medical Examinations.—The report of this board stated that out of 756 candidates for license, during the past year, 667 appeared before the Board of the State Society, 43 before the homœopathic board, and 46 before the eclectic board. There were 123, or 16.2 per cent., rejected.

The Modern Pharmacology of Iron.—Dr. REYNOLD W. WILCOX of New York read this paper. In it he discussed briefly the chemical properties of an ideal preparation of iron.

Tic Douloureux and Other Neuralgias from Intranasal and Excessive Accessory Sinus Pressures.—Dr. SARGENT F. SNOW of Syracuse presented this paper. He said that, in the twenty chronic cases that he had observed and treated, he had seen none that required excision of the nerve to obtain relief. Each one had presented well-marked intranasal pressure or collections in some of the sinuses. A pain radiating from the bridge of the nose outward or upward usually indicated involvement of the anterior ethmoids; a deeper or more intense pain under, or behind the eye, pointed to the middle and posterior ethmoids; while still deeper, splitting pain, radiating outward from the center of the head, pointed to involvement of the sphenoid. It could not be denied that many cases of tic douloureux resulted from intranasal pressures, and treatment directed to the removal of such pressure often relieved the tic.

Traumatic Hemorrhage Over the Third Anterior Frontal Convolution; Operation; Removal; Recovery.—Dr. W. C. KRAUSS of Buffalo reported an interesting case of this kind. The patient was a robust man of fifty-six years, who had formerly enjoyed good health. He fell from a trolley car, striking the head and shoulder. That night he suffered intensely from pain in the occipital region. The next day he read and conversed with his family and seemed to be improving rapidly, but the following morning he began to talk unintelligibly and incoherently. Finally surgical aid was invoked, and he was operated on by Dr. M. Hartwig. A small localized hemorrhage was found on the side of the head opposite to the one receiving the blow. No change in speech occurred for many hours after the injury. The vessel injured was a small vein of the pia, apparently situated just anterior to the speech center. The diagnosis of hysteria was not entirely excluded until the occurrence of facial epilepsy on the right side, associated with aphasia. The man was restored to perfect health in a few weeks.

Enuresis.—Dr. GEORGE E. BEILBY of the State Industrial School at Rochester, read this paper. He said that enuresis was most common between the third and tenth years of life, and affected both sexes about equally. There were, however, a large number of cases seen in adolescence in institutions, especially among males. These cases were especially difficult to treat. In the State Industrial School at Rochester he found from 4 to 10 per cent. of the population suffered from enuresis. In other institutions the percentage of such cases was even higher. The author had records of seventy-five well-marked cases. Only two of them were imbeciles, and in only seven were there marked signs of degeneracy. Examination of the urine revealed no marked abnormalities, nor was there evidence of calculus of or vesical irritation. In only a few was there any marked phimosis. He, therefore, concluded that the majority of the cases must be explained by irritability of the lumbar enlargement of the cord. Sixty had nocturnal enuresis; two diurnal, and thirteen both nocturnal and diurnal. Six had incontinence of fæces as well as of urine. The duration of the enuresis varied from a few months to several years. Many of these patients were known to be chronic and excessive masturbators; indeed, such a history was elicited in seventy-one of the cases. The ones proving most obstinate were those in which masturbation was most excessive. Treatment should consist in an appeal to the moral sense, and in improving the physical condition and attempting to relieve the irritability of the lumbar cord. Circumcision was performed in his cases, almost as a routine, even when there was no phimosis, because of the profound mental impression it produced, and its tendency to prevent masturbation. Cold spinal douching and counter-irritation over the lumbar cord were indicated, and antispasmodics were generally beneficial.

Toxæmia in Tuberculosis of the Cervical Lymphatic Glands.—Dr. ARTHUR W. ELTING of Albany reported a case of this kind. The patient was twenty-six years of age, and presented an enlargement of the right side of the neck. At first, a diagnosis of Hodgkin's disease was made. The glandular mass was removed by operation, the procedure being greatly facilitated by division of the sternomastoid. This muscle was sutured, with good functional result. Microscopical examination showed the typical appearance of tuberculous glands with caseation. A few tubercle bacilli were also detected. The blood picture presented before operation certainly suggested Hodgkin's disease, yet the blood returned to the normal after recovery of the patient. It was worthy of note that the patient's condition became very critical after the operation, and lasted for some time. This was probably due to the entrance of a large quantity of toxins into the circulation as a result of the manipulations incident to the operation.

Dilated Urachus.—Dr. C. F. TIMMERMAN of Amsterdam read a report of such a case and presented a specimen.

Insufficiency of the Pylorus.—Dr. MARK I. KNAPP of New York read this paper, based on an experience in fifty consecutive cases. He said that it was well known that pyloric stenosis was the forerunner of insufficiency of the pylorus. In insufficiency there was very little chyme, and what was present was coarse. It should be remembered that absence of chyme was not due to hypermotility. The immediate cause was a chronic inflammation of the pylorus. Insufficiency of the pylorus presented no symptoms. Alkaline treatment was appropriate for this condition.

Symposium on Diabetes.—This comprised the following papers:

Pathology.—Dr. R. M. PEARCE of Albany discussed this topic. He said that in only half of the cases of diabetes could any gross lesion of the pancreas be found. The most important work in the histology and pathology of diabetes had been done in this country in the last three or four years, inaugurated by Opie. He showed two definite forms of chronic pancreatitis. (1) an interlobular; (2) an interacinar form. The latter also invades the islands of Langerhans. In the first variety, diabetes practically never occurred, but in the second variety, diabetes was present in one out of the twenty cases studied. Dr. Pearce said he had collected twenty-three cases of cancer of the pancreas, and in only three had glycosuria been present. Two of these three were typical cases of diabetes. In both diabetic cases the cancer was in the heads of the pancreas and obstructed the pancreatic duct. In both cases also, it should be noted, there was distinct involvement of the islands of Langerhans by fibrous tissue. He had traced the development of these islands, and had found that they arose from the true secreting glands, but, at a certain stage, took on a new form and became thoroughly differentiated. It was well known that there was seldom any such special differentiation without the structure being endowed with a special function. It was also significant that the islands of Langerhans were more resistant than other parts of the pancreas to destructive processes. Dr. Pearce said he did not believe that all forms of diabetes were due to the pancreas, but recent additions to our knowledge had certainly given us a more satisfactory basis.

Physiological Chemistry.—Dr. DAVID EDSALL of Philadelphia, Pa., discussed this subject. He said that it was no longer believed that there existed, in the blood-stream, any important glycolytic ferment. It had been shown that diabetes did not occur if the liver as well as the pancreas, were extirpated in birds and frogs. It was a remarkable fact that in birds, extirpation of the pancreas caused a disappearance of the glycogen from the tissues and an excess of sugar in the blood and yet glycosuria does not occur. Sugars were probably far more varied in their nature than they were now known to be. The difficulty in diabetes might be one of glycogen construction, or one of excessively rapid conversion of glycogen into sugar.

Medical Treatment of Diabetes.—Dr. WILLIAM H. THOMSON of New York read this paper. He said that he could contribute very little to this necessarily empyrical subject, except by citations from his own experience. A glycosuria lasting more than a year, he generally pronounced diabetes. The presence of diacetic acid in the urine was generally indicative of confirmed diabetes. The younger the patient, the worse the prognosis. The daily output of urea should be determined, for, even though the patient were obese, if the percentage of urea were continuously high, emaciation was really going on. He very rarely prescribed codeine or any other of the opium derivatives, in diabetes; on the contrary, he condemned their use, for he believed that medicines of this class—"functional medicines"—could not permanently affect the tissues. For many years he had advocated cod-liver oil for diabetes, and especially urged its use in young subjects. This was an undoubted empirical fact, though he was unable to state the nature of its action in this disease. However, obesity contraindicated the use of cod-liver oil, and its administration was not advisable in persons leading a sedentary life. Next to cod-liver oil he would place iron. Arsenic was also beneficial, and was given by him usually in the form of arsenious acid. When the output of sugar was so large as to require prompt relief he gave fifteen grains each of antipyrin and benzoate of sodium, four times a day. After a time he would substitute fifteen grains of aspirin and ten grains of bismuth salicylate. Alkaline waters had for a long time deservedly held a high place, but it should be remembered that the continued use of such waters in persons who were emaciating was always prejudicial. However, diabetes was always a very grave disease, because it necessitated the elimination of an important element from the diet and eventually the system would secure the sugar it so much craved by the conver-

sion of its own proteids. Then would come a condition of toxæmia An impending diabetic coma was often heralded by the kidneys in the deposition of a peculiar form of casts.

General Management of Diabetes.—Dr. F. C. SHATTUCK of Boston read this paper. He said that very little could be done in the preventive treatment of this disease. Except in very mild cases, the diet should be at once restricted. If diacetic acid and acetone were present in the urine, a radical change in diet was dangerous. The patient should be weighed at short intervals, and the patient should learn, in a general way, the quantity of each of the articles of diet to be taken. In the milder cases, a strict diet should be maintained for a month or two, and then the toleration for starch should be tested. In the severer cases one must be more careful in giving bread. He made but little use of the manufactured diabetic breads, having found them unreliable. No diabetic bread, which was palatable, was safe to use for any great length of time. If, in spite of a rigid diet, the sugar in the urine persisted, a certain amount of bread should be allowed. Diabetics were sensitive to cold, and therefore should be warmly clothed. Rest, both of body and mind, was highly important. Exercise should be taken in moderation, and the best general rule in this regard was that, if after exercise and rest for an hour, the feeling of weariness had not passed off, too much exercise had been taken.

The Occurrence of Diabetic and Non-diabetic Glycosuria in the Same Individual.—Dr. HEINRICH STERN of New York presented this paper. He said that the diabetic state might be well established before glucose was excreted by the urine. Diabetic glycosuria was nothing more than the salient feature of the second stage of the diabetic deterioration. Glycosuria was a symptom of manifold other disturbances of ectogenous as well as of endogenous causation. With the assistance of various discrepant factors we were enabled to differentiate clinically between the diabetic and non-diabetic forms of glycosuria. Duplex mellituria was the result of two concurrent or intercurrent affections of dissimilar character having the one symptom, glycosuria, in common. The recognition of duplex mellituria depended on the alternate prominence of one set of symptoms, including the respective glycosuria.

Conflicting Claims of General Education and of Professional Education.—ARTHUR T. HADLEY, LL.D., president of Yale University, delivered an address on this theme before the society at its evening session, held in the Senate chamber. He said that the period of technical training requisite for the modern physician had become so long as to make it a burden to all, and an insuperable burden to those who were poor. The difference at the present time between the professional school and the college was not so much in the things studied as in the atmosphere in which they are studied. In the professional school there was a greater intensity of application, but this was secured by a sacrifice of a certain breadth of view; indeed, the very intensity of the effort in the professional school tended very strongly to an undue predominance of the commercial idea. The speaker advised those contemplating a professional career to obtain some of their preliminary professional education in the broader atmosphere of the college. The sooner a man's brain began to turn to his life work, the better, but the later a man's horizon tended to be narrowed to the sphere of his life work, the better also. He would not shorten the college course, but would include within it all the scientific studies which such a course could be made to convey, and would secure a fuller recognition by our professional schools of the results of such study. Our professional men must be men first and technologists afterward. Any true system of education should find a way of helping men to broaden their mental and moral horizon even while they were learning to concentrate their vision on their special fields of activity.

President's Address: "The Present Status of the Medical Expert."—Dr. ALGERNON T. BRISTOW of Brooklyn took this as the theme of the annual address of the president. After quoting some of the vigorous denunciations of the medical expert emanating from the bench, he asked if it were possible, or even probable, that all the members of the medical profession were liars and perjurers, and that all the noble and true men were in the legal profession. Certainly, the history of the medical profession showed that it never shrank from duty, and that it was not lacking in unselfishness and moral courage. If medical testimony were now without value, it was reasonable, the speaker thought, to look elsewhere for the cause than to the personal character of medical experts. Some judges admitted that the system of medical testimony was inherently faulty, but excused this state of affairs on the specious plea that a change in the mode of legal procedure would result in chaos and disaster. It was a pernicious rule that held that a technical education of three or four years in a medical school was on a par with the man having the same education, with added years of experience. It was this rule which led to much conflicting medical testimony, and brought such testimony into disrepute with the public. Strenuous efforts were made, at the cost of much time and money, to secure an unbiased jury, and yet just an opposite course was pursued in the calling of medical experts. What wonder, then, that little weight is attached to such prejudiced testimony! The remedy for all this was to be found in modifying the present objectionable legal procedure. The hypothetical question was a source of much confusion and error. It was very commonly framed in such a way as to suppress part of the truth, and yet the witness was sworn to tell the *whole* truth. The medical profession was weary of the cheap and violent denunciations from the press, denunciations which were wholly unwarranted in view of admissions made by the legal profession regarding the glaring defects of their system. It was admittedly impossible to convict the expert of perjury because it is opinion evidence, and yet one judge went so far as to suggest that a remedy for the existing evil might be found in the expulsion of the expert from his medical society. Doubtless, the problem was a difficult one, but the legal profession had shown a decided disinclination to meet the medical profession half way in the effort to improve the mode of procedure. A good deal could be accomplished in the way of reform by the enactment of laws which would secure the proper qualification of experts. The selection of the experts for both sides, if made by the bench, would eliminate much biased testimony, and if the experts were paid by the State, another step in advance would be made.

SECOND DAY—WEDNESDAY, JANUARY 27.

Future Meetings of the Society.—In accordance with suggestions contained in the president's address, the society voted in favor of continuing the semi-annual scientific meetings, holding them successively in Buffalo, Rochester, Syracuse, and New York. It was also decided that hereafter the annual meeting in Albany should begin on Tuesday afternoon and continue until Thursday evening, and that the annual dinner be held on that evening.

The Submerged Tonsil.—Dr. THOMAS J. HARRIS of New York read a paper with this title. He said that the term should not be confined to the moderately enlarged tonsil partly hidden by the faucial pillar. The inflammatory, hyperplastic form was the one found in the submerged tonsil. Among the symptoms of the condition were, repeated attacks of peritonsillar abscess and of non-suppurative tonsillar inflammation; pain, vaguely referred to the throat, and perhaps associated with a well-developed follicular condition; a constant collection of mucus in the throat; earache, and annoying cough. It should be remembered that a peritonsillar abscess was at the outer side of the tonsil. A knife, carried parallel to the axis of the tonsil and between it and the anterior or posterior pillar, as the case might be, would enter the base of the

abscess without difficulty or risk of wounding any important blood-vessels. As ordinarily done, tonsillotomy was an incomplete operation. His own practice was to endeavor to secure complete removal of the tonsil. The treatment of the submerged tonsil was essentially surgical and consisted, first, in freeing the adherent anterior pillar, and, if necessary, the posterior pillar; and, secondly, the removal of the tonsil in whole, or in part, the separation of the adherent pillar was an indispensable step in the operation. After cleansing the tonsil and throat with Dobell's solution, both tonsils should be painted several times, at intervals of a few minutes, with a 10-per-cent. solution of cocaine. A final injection into the tonsil of a 2 or 3-per-cent. solution of this drug was made. The adhesions to the pillars must be carefully separated and the exposed tonsil removed with the tonsillotome or other instrument. His personal preference was for the tonsillar punch. After the operation, the patient should remain indoors and gargle the throat with an alkaline solution. The use of an emulsion of orthoform would relieve the soreness of the throat. The other tonsil might be relieved the following week.

Some Phases of Chronic Laryngitis.—Dr. Z. L. LEONARD of New York was the author of the paper. In it he reported two or three cases illustrative of different types of the disease, and emphasizing the fact that chronic catarrhal inflammation of the larynx was by no means incurable, and was deserving of the most careful and painstaking management. The important points to remember were the benefit accruing from rest of the part and a change of residence; sometimes, also, from change of occupation. The importance of prophylaxis should not be forgotten.

A Plea for Accurate Knowledge in the Diagnosis and Treatment of Chronic Suppurative Otitis Media.—Dr. J. F. MCCAW of Watertown read a paper with this title. He said that when pain supervened upon a chronic discharge it was a warning of disastrous results likely to follow if this symptom was unheeded. At the outset, every case of chronic suppuration of the middle ear should be examined carefully for obstructions of the nose and nasopharynx, and all such obstructions should be removed. Adenoid growths in the nosopharynx were the most common and fruitful cause of suppuration of the middle ear. The location of the perforation should be determined, and sufficient drainage secured. A perforation, situated high up, usually pointed to necrosis of the ossicles or inflammation of the structures of the attic, and a tendency to slow healing. The author's special plea was for treatment based upon the pathological conditions present.

Irritability of the Bladder.—R. L. DICKINSON of Brooklyn urged thoroughness of investigation, giving a full list of causes. Cases formerly obscure were now cleared up by the cystoscope. Inflammation of the trigone was the most common cause. Masturbation-hyperæmia was studied, and its diagnosis made by the corrugated enlargement of the labia minora, fourchette, or prepuce; by the dilatable meatus, often admitting the finger tip; by the tiny lateral flaps of the meatus—hypertrophies of the anterior portion of the hymen, due to repeated tractions. Degrees of downward dislocation of the urethra and bladder, sufficient to cause obstinate trouble, might require the upright position to detect. Prolapse of bladder and urethra in women of relaxed habit, or in those subjected to hard labor, or in elderly women, called for lifting by ventral fixation, anchoring the tolerant top of the bladder to the anterior abdominal wall.

Fifteen Years' Experience with Uterine Fibroids.—Dr. W. E. FORD of Utica read this paper, which was based on 162 cases in which the ultimate result could be stated. Of this number, 114 were married, 37 were single, and 11 were widows. Of the 162 cases, 96 were treated by galvanism, most of them during the early years of his experience. He made use of a forty-volt current of a strength of 50 to 150 milliamperes. Seven of these 96 cases recovered, as indicated by the disappearance of the symptoms and of the tumor. Twenty-six cases were improved as to the symptoms of hemorrhage and pain. A few of these relapsed, and were treated again, and then they remained well for at least five years. Twenty-five cases had been followed for five years or more. In these cases the tumor became smaller and the patient's remained well. One patient died as a direct result of infection, an acute inflammation having arisen from an old and unrecognized gonorrhœal salpingitis. This was the only accident observed in connection with the galvanic treatment of fibroids, and he had seen no reason to attribute, as many had done, all sorts of bad results to this mode of treatment. Thirty-one women were treated by curettage, tying the uterine arteries per vaginam, or by the administration of ergot, thyroid extract, etc. Of this series, twenty-four were temporarily improved, but the tumors were not appreciably diminished. His experience with the tying of the uterine arteries was not fortunate, and he soon abandoned it as hazardous, difficult, and useless. He did not think he secured any positively good results from the use of thyroid extract, but he had lately succeeded in stopping the bleeding by the administration of adrenalin or suprarenal extract. Sixty-one women were operated on, six early ones by abdominal section with external treatment of the stump. Two out of these six died; one of them, however, from a second attack of cerebral hemorrhage. Thirty-four of the patients were operated on by supravaginal amputation of the stump by Baer's method. Fifteen women were treated by morcellation, and eleven by evisceration through the vagina. He was of the opinion that probably not more than 20 per cent. of the cases of fibroids demanded operation. He had known small fibroids to remain stationary for many years.

Results in Diffuse Septic Peritonitis Treated by the Elevated Head and Trunk Position.—Dr. RUSSELL S. FOWLER of Brooklyn read this paper, which was based on an experience in one hundred cases. No case, no matter how severe, was refused operation. Sixty-seven patients recovered. The abdomen was entered through a rather small incision, and accessible infection was sponged away with bichloride sponges. The immediate neighborhood was flushed out with a solution of peroxide of hydrogen diluted with an equal quantity of soda solution. This application was followed by washing with saline solution at 110° F., and the parts dried. Other collections of pus were then searched for, and treated in a similar manner. Finally a Chamberlain douche-tube was placed in the pelvis, and then in other parts of the abdominal cavity, and the peroxide-soda solution introduced throughout. The entire abdomen and pelvis were then flooded with saline solution. At no time were the intestines allowed to escape through the wound. The flushing should be rapidly done with a large tube and kept up until the wound was sutured. A glass tube was inserted into the pelvis and brought out through the abdominal wound. Eighty patients were so treated. In twelve cases bundles of wick-drains were used. The glass tube was dressed independently of the operation wound. Directly after the operation the patient was placed in the elevated head and trunk position. The elevation of the bed should never be less than one foot. Before the employment of this elevated postion, 25 per cent. were saved. Of the thirty-three deaths, seventeen occurred within twenty-four hours of operation. These patients were profoundly septic, and were practically moribund at the time of the operation. All but one of the cases operated on showed distinct improvement almost immediately after the operation.

Asthenopia; a Clinical Study.—Dr. D. H. WIESNER of New York was the author of this paper. He pointed out that hysterical or psychical asthenopia did exist and must

be differentiated from other forms by a process of exclusion. In the ordinary forms of asthenopia there was usually more or less headache. If the pain were near the eye, it usually indicated a refractive origin; if the pain were further away, the asthenopia was usually of muscular origin. The headache of eye-strain usually grew worse as the day wore on, but the patient awakened free from pain. Blurring of vision was another very common symptom and occurred both with distant and near vision, particularly with the latter.

A Preliminary Note on the Relation between the Muscles of the Eye and Those of Other Parts of the Body.—Dr. LUCIEN HOWE of Buffalo presented this communication. He said that it was possible to obtain a numerical expression for the general muscular strength of the body. Sargent's method of doing this was demonstrated. It was also possible to obtain an expression in terms of a prism, of the strength of the muscles of the eye. These two results bore a certain relation to each other, a point to which he believed attention had not been previously directed. The practical application of this knowledge was that, by strengthening the muscles of the body, one could strengthen the muscles of the eye.

Diagnosis and Treatment of Glaucoma.—Dr. D. B. ST. JOHN ROOSA of New York presented this paper. He said that when a person in middle or later life came with a weeping conjunctiva, with no sticking together of the lids in the morning, with a red zone around the cornea, with considerable dimness of vision, and with a distressing so-called neuralgia of the eye, the physician should be on his guard for glaucoma. If in addition to these symptoms there were anæsthesia of the ocular conjunctiva, and palpitation showed an increased tension of the eyeball, a presumptive diagnosis for glaucoma might be made. A conformatory test was to be found in physostigmine or eserine, preferably dissolved in oil because less irritating to the eyeball than aqueous solutions. With a two-grain solution of eserine one could quiet the terrible neuralgia, and, perhaps, mitigate the symptoms so that an operation would not be required for a time, and, possibly, not at all. There were only two kinds of glaucoma, acute and chronic. But of these there were subdivisions, such as primary and secondary glaucoma.

A Study of the Climate of Long Island.—Dr. W. H. Ross of Brentwood, L. I., read this paper. He said that although Long Island was one of the oldest settled portions of the United States, little seemed to be known of its healthfulness by the medical profession in general. It was, for the most part, a dry, sandy plain, rising gently from the south shore to the north. The island was of glacial formation, consisting of sand, gravel, and an occasional layer of clay. As deep as the deepest wells had been bored, little but pure laminated sand and gravel had been found. The strata sloping to the south determined the ground water currents; hence, wells should be located to the north of a dwelling, and cesspools to the south. Fogs were infrequent over the major portion of the island. The water supply of the island was very pure, there being many never-failing springs whose waters, coming up through the sand, had a temperature of 50° F the year round. The author's deductions concerning the climate were based on meteorological observations made by him during a period of ten years. The mean summer temperature was found to be 70°, and the annual range only 30°. The eastern portion was five degrees cooler than New York City in summer, and sixteen degrees warmer than the rest of the State in winter. This difference was due to the modifying effect of the ocean. The nearest approach to a maritime climate along the coast was eastern Long Island. The relative humidity was low, the yearly average humidity being 72.75°. The average number of clear, and partly clear, days in the year was three hundred, only thirty less than El Paso, Tex. and Phœnix, Ariz. Long Island was favorably placed to receive the prevailing southwest or south wind in summer, being situated nearly at a right angle to the mainland. The breeze in summer was cooled by a large expanse of pure water. The pine forest region was six miles wide and sixty miles long; there was no other evergreen forest of greater size in the State nearer than the Adirondacks. Such forests had a powerful purifying effect on the atmosphere. The therapeutic elements desired in a climate were a pure air, free from organic or inorganic elements and without excessive dampness; an abundance of sunshine; a sandy soil; and an equable temperature. All these Long Island possessed; and, in addition, there were the antiseptic emanations from its pine forest.

The two healthiest counties in the United States were Suffolk, L. I., and Berkshire, Mass. The inhabitants of the island showed great longevity; thus, 526 out of 770 deaths in 1891, were between 70 and 90 years. Out of 3,935 deaths, over twenty years of age, in 1885-86-87, 1,394 were between 70 and 90 years, and 642 between 80 and 100 years. When the climate of Long Island was better known, fully understood, and medical men appreciated the fact that this island was really a pier, extending a hundred miles into the Atlantic Ocean and attached to the greatest city in America, Long Island would reach its manifest destiny and become one great health resort.

Placenta Prævia.—Dr. THOMAS P. SCULLY of Rome read this paper, based upon a personal experience with nine cases. Five of these were treated by the older methods, and four died from puerperal septicæmia. The remaining four were treated by modern antiseptic or aseptic methods, and only one of these terminated fatally. He said that the Braxton-Hicks method of bipolar version was preferable, when it was applicable to the individual case.

The Treatment of Cancer by Its Own Toxin.—Dr. P. J. MCCOURT of New York read a paper on this subject. He said that the method of preparing this toxin had been described by him in a paper read in November, 1899. In cases of cancer, death commonly resulted from a toxæmia produced by the cancer cells. The accuracy of this statement, he declared, was attested by a very large number of cases. In his first communication he had made no claims further than that this treatment afforded marked relief. Since that time he had furnished the toxin to physicians applying for it in all parts of the world. All stimulants, and especially malt liquors, were poison to the cancer patient, and served to hasten the fatal climax. The diet should be carefully regulated, and but little meat should be taken. A suitable dose of the toxin was usually administered morning and evening when the stomach was empty. It produced the following effects: (1) Diuresis and the discharge of much fetid dark urine; (2) local exudative erythema; (3) diarrhœa, and (4) diaphoresis. There was rarely elevation of temperature, and all symptoms were markedly relieved in a short time. In 5 per cent. of advanced and extremely malignant cases this method of treatment was entirely valueless; 90 per cent. were relieved of pain, fetor, hemorrhage, insomnia, vesical and rectal tenesmus, etc., general improvement occurred and life was materially prolonged. In 14 per cent. of the cases indurated glands had become normal, ulcers had healed, body-weight had increased, there had been complete cessation of objective and subjective symptoms, and the patients were apparently cured.

Recent Researches in Radioactivity and Electricity—Their Bearing on Radiotherapy; Legal Status.—Dr. J. S. WIGHT of Brooklyn read a paper with this title. He said that he had been able to show that the high-frequency discharge would coagulate blood and serum-albumin, in part due to the formation of nitric acid from the air; but there was no destruction of tissue with ordinary care. He had employed this in connection with his method of electrical grafting.

Electrical Grafting.—In carrying out this method, the surface should be made sterile and then curetted thoroughly.

While still oozing, grafts should be applied, and the high-frequency discharge applied with a pointed electrode until clotting was firm and the grafts were fixed on the dry surface. The serum squeezed out in the process of clotting should be sponged off, and the part dressed with three per cent. carbolized vaselin. This dressing would not adhere. It should be renewed on the third day. Healing would be hastened by an application of the secondary Rōntgen rays. These rays were produced by an apparatus which Dr. Wight exhibited. These rays were not reflected, but were truly secondary, being emitted at the elbow of the tube from a plate of metal or paraffine. A number of other interesting discoveries were briefly mentioned.

Lesions in the Structures Surrounding the Knee-joint—Dr. NATHAN JACOBSON of Syracuse read an abstract of his paper on this subject. He classified these lesions as: (1) those the direct result of traumatism: (2) those caused indirectly by injury, and (3) those without known cause. Of the more uncommon disturbances was the rupture of the quadriceps extensor tendon or of the ligamentum patellæ. Another lesion was periostitis of the head of the tibia, usually the result of slight injury. Bone tuberculosis sometimes occurred, and was often excited into activity by traumatism. Cases illustrating these various conditions, were reported.

Report of 615 Surgical Cases at the Albany Hospital.—Dr. ALBERT VANDER VEER of Albany presented in this paper an account of his service at the Albany Hospital for one year, ending March 1, 1903. Referring to fractures of the lower jaw, he said that he had at last settled down to the treatment of these cases by an interdental splint. In cases of tuberculosis of the glands he advised early operation. There were 178 abdominal sections, 18 of which were cholecystotomies. All of the latter recovered. Where sinuses persisted, they could often be induced to heal promptly by dropping in a few drops of pure carbolic acid. Occasionally it was necessary to repeat this application. There were two cases of uterus bicornis, plates of which were shown.

A Case of Gunshot Wound of the Brain.—Dr. JOHN A. WYETH of New York reported this case. The patient was a man of twenty-three, who had received a pistol-shot wound of the head on August 11, 1903. The wound was one inch to the right of the median line, and about the same distance from the junction of the interparietal with the frontoparietal suture. No effort was made to locate or remove the missile. There was mental impairment from the time of the injury, and, on coming under the speaker's observation, five months later, he talked incoherently and was restless. The bullet was located. The skull was cut through just above the eyebrow, and a rubber drainage tube was inserted to drain an abscess that had formed. Although there had been considerable loss of the substance of the right anterior lobe, the man recovered promptly with only slightly diminished intelligence.

Tuberculous Myositis; Report of a Case.—Dr. WILLIAM B. BRINSMADE of Brooklyn reported this case. There was no family history of tuberculosis. The patient was a well-developed and apparently healthy woman who, five months previously, had been struck on the outer aspect of the leg by a falling coal-scuttle. Examination showed a fairly symmetrical and hard enlargement extending from the ankle to the knee. The skin over the tumor was movable. A provisional diagnosis of sarcoma was made, and a section was removed for further examination. This showed typical tuberculous inflammation. Ten days later a long incision was made over the fibula. This showed the muscle to be pale in color and soft, and studded with six grayish areas of the size of a hickory nut. On cutting into these areas, caseous material, typical of tuberculosis, was revealed. The woman made an uninterrupted recovery, and was still well at the present time, four months after the operation. The disease was so rare, Dr. Brinsmade said, as to make it a curiosity.

Associated Cases of Staphylococcus Aureus Infection.—Dr. ARTHUR G. ROOT of Albany reported in this paper a group of such infections occurring in the State Industrial School at Rochester.

The Non-operative Treatment of Trachoma.—Dr. FRANK J. PARKER of New York read this paper. He said that in the non-inflammatory variety which was seen in our schools, the treatment should aim to be germicidal, and also to restore the hypertrophy to the normal condition. He believed the cases for operation should be carefully selected, and that indiscriminate operation was capable of doing much harm, and should never be employed where there were small hard follicles, either alone or with the soft variety. He believed in operation in all well-marked cases of follicular trachoma of the soft variety as the best way of shortening the treatment. It was highly important to improve the patient's surroundings and general health. In the first and second stages of the soft follicular variety, a hard cotton application should be dipped in a 1 to 500 bichloride of mercury solution, and, after cocainization, this solution should be vigorously rubbed into the lids, especially along the tarsal cartilage. This should be done three times a week, and if there should happen to be an excessively violent reaction, ice-clothes should be used. The patient should use at home some organic silver solution, which should be dropped into the eyes night and morning. He had used a 10-per cent. protargol solution with fair results, but argyrol had served him better. He regarded it as the ideal salt of silver. In any case, the treatment must be persisted in until a complete cure was effected.

Aphasia and Agraphia.—Dr. EDWARD D. FISHER of New York read this paper. He said that the various forms of aphasia were divided into sensory and motor, the former being subdivided into intercortical sensory aphasia. In the one case, the perceptive centers of spoken and written language were involved; in the latter only the association fibers connecting these centers were affected.

Motor aphasia and agraphia were both defined as a loss of the memory of the necessary coördination of the muscles of articulation, on the one hand, and writing on the other. There might be also sensory agraphia when the memory of the optical picture to be reproduced was lost, although, as in a case cited, these patients might write accurately from copy. Language being the vehicle of thought, any affection of it must, to some degree, involve the integrity of the mind. Especially was this seen in sensory aphasia, where the memory of the character and uses of an object was more apt to be impaired than in motor aphasia.

Our accepted location of the speech centers in the left hemisphere had been thoroughly established by pathological studies, although much remained to be studied as to the subdivision of the special centers. There was some doubt, according to the writer, as to the location of the writing center being in the second frontal convolution, several cases being cited in which a lesion in that region did not cause agraphia. There would seem, however, from analogy with speech, that there was such a center. There was no doubt, however, that speech and writing were closely allied, as shown clinically by the fact that agraphia and aphasia were usually present together.

Symposium on Abdominal Pain.—This comprised the following papers:

Abdominal Pain in General.—Dr. JOHN H. MUSSER of Philadelphia, Pa., opened the symposium with a consideration of this topic. Speaking of spasm, or rigidity of the abdominal muscles, he said it should be remembered that, in women with enormously distended and relaxed abdominal walls, rigidity was not likely to be present. If toxæmia were present, or there were a moderate leucocytosis, too much stress must not be laid upon muscular spasms as an evidence of pain. On the other

hand, in athletic individuals even moderate abdominal pain was likely to give rise to excessive muscular spasm. It had long been known that in some cases of Bright's disease, particularly in pregnant women, pain occurred in the upper half of the abdomen as a forerunner of an attack of uræmia. Then, there might be cases of supposed abdominal pain dependent upon hysteria. In considering abdominal pain, one should not forget the occurrence of rheumatism of the diaphragm and diaphragmatic pleurisy. With the onset of pneumonia, particularly in children, the symptoms complained of might be entirely abdominal, and lead to a suspicion of appendicitis or a localized peritonitis. Pain due to gastric disease was not by any means confined to the region of the stomach. Pyloric spasm was often confounded with gall-bladder disease. A large proportion of the cases of supposed gastralgia that he saw proved to be cholelithiasis. Pericarditis and angina pectoris were well known to be associated with pain referred to the abdomen. Every known method of investigation must be called to our aid in differentiating gastric, hepatic, renal, and pancreatic pain. The disappearance of pain was often also of much significance, pointing frequently to the onset of toxæmia. Again, there were cases in which pain was absent when it should be present. A notable example of this was intestinal obstruction with paresis of the bowel.

Abdominal Pain Referable to the Abdominal Walls.—Dr. JOSEPH D. BRYANT of New York read this paper. He said that inflammation of the visceral layers of the peritoneum did not cause pain of such severity as to be of much diagnostic importance in most instances. The nerve supply of the abdominal walls should be borne in mind in connection with this subject. A hyperæsthetic surface sometimes overlaid an inflamed area of peritoneum. Involvement of that portion of the pleura supplied by the dorsal nerves would sometimes cause pain, hyperæsthesia and rigidity of the abdominal wall. An infection localized in the abdominal wall itself might be mistaken for intra-abdominal involvement.

Abdominal Pain of Intestinal Origin.—Dr. FREDERICK HOLME WIGGIN of New York presented this paper. He said that abdominal pain was common to all disorders of the intestine. In a general way, sharp persistent abdominal pain indicated involvement of the peritoneum, while dull aching pain indicated involvement of the connective tissue. Tenesmus pointed to implication of the lower third of the intestinal tract. Colicky pains occurring several times a year, in a person not constipated pointed strongly to ventral stenosis. Involvement of the colon was shown by diarrhœa, limitation of the pain and sensitiveness of the course of the large bowel. Colicky pain in the left iliac fossa with tenesmus and blood-stained stools, suggested inflammation of the sigmoid flexure of the rectum. In disease of the upper part of the duodenum there was pain in the right hypochondrium and occurring a few hours after eating. The diagnosis of appendicitis should never be made until after exploration of the chest had excluded disease of the lungs or pleura. Severe abdominal pain in the region of the umbilicus, associated with constipation and collapse, suggested external hernia, and should lead to a careful examination of all the various hernial openings and also a search for a tumor in the linea alba. Subacute symptoms of obstruction, occurring in a man over forty years of age, giving a history of constipation and associated with rapid distention of the bowel, pointed to volvulus. In all cases of persistent abdominal pain of obscure origin, exploratory operation should be done.

Dr. ROBERT F. WEIR of New York discussed the subject of abdominal pain. He called attention to the recent communication from Dr. Ellsworth Eliot of New York on the behavior of the aortal arches as an aid to diagnosis. If, with the thumbs directed toward the sternum, and the fingers crowding the aortal arches inward and toward the vertebral column, an abnormal resistance was encountered, it was very significant of some pathological condition in the region of the liver, pancreas, duodenum, or pylorus, and was sometimes present when there was no rigidity of the rectus muscles. With this resistance, there was oftentimes an additional pain. Dr. Eliot had met with one case of pancreatitis in which leucocytosis was present. So the surgeon could no longer rely implicitly upon absence of leucocytosis as an indication of pancreatitis. Dr. McBurney had told him of one case in which the rigidity of the abdominal wall was not due to some intraabdominal lesion, but to beginning tetanus. Although it had been shown that "McBurney's point" did not accurately represent the position of the appendix, the method of examination known as "finger pressure" suggested by McBurney was in itself so valuable as to warrant the association of his name with it. It was often exceedingly difficult to feel the appendix, and it was well to remember that this palpation could be very greatly facilitated by directing the patient to raise the leg a little outside of the the median line. This would cause the psoas muscle to contract, and as the appendix was usually resting on this muscle or near it, the appendix would be lifted up within reach of the examining finger. In the case of a young child, much information could be obtained by passing the finger up into the bowel.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 1, 1903.

PEARCE BAILEY, M.D., PRESIDENT.

A Case of Brain Tumor with Autopsy.—Dr. WILLIAM M LESZYNSKY reported this case. (See page 165.)

Dr. J. F. TERRIBERRY said that he had seen this case at the Manhattan Eye and Ear Hospital. The astereognosis was one of the most prominent symptoms at that time. The young woman had spasmodic contractions of the face muscles, first on one side and then on the other. The importance of the astereognosis as a localizing symptom had been forcibly impressed upon him by this case. If these symptoms, coming from the basic area of the brain, had occurred earlier, they might have led to an erroneous diagnosis.

Dr. GEORGE W. JACOBY said that the most interesting part of the report to him was the demonstration of the *x*-ray plates. In the skiagraphy of tumors of the brain we possessed a very valuable adjunct, but we should insist upon more precision in the description of these examinations. Over a year ago he had exhibited to this society two skiagraphs of a case of tumor of the brain, taken during life. The patient was subsequently operated upon, and the tumor removed, and the patient lived five months longer. This case proved the feasibility of obtaining skiagraphs of practical value in these cases of tumor of the brain. Oppenheimer's experiments in this direction were very interesting. He had experimented with a hardened tumor in the brain and with a hardened tumor within the skull, and had succeeded admirably, but had failed on attempting to photograph brain tumors during life. Dr. Jacoby said that he had repeated these experiments, and had discovered that when soft or fresh tumors were used the result was not successful. Since that time he had made many clinical examinations on supposed brain tumors without obtaining a single positive result until the one presented by him a year ago. This experience showed that one should work with a known tube and with a known exposure to determine what would give a complete transillumination of the skull. Having done this, the minimum exposure should be used—say, seven and one-half or eight minutes—and then each successive exposure should be made a little longer. In his own successful case exposures of ten and a half and eleven and a half minutes respectively were successful, whereas longer and shorter exposures led to failure. It has been thought by some observers that the result would only be

successful with a thin skull and a hard tumor, but in his own case the bones of the skull were thick and the tumor friable.

Dr. Leszynsky said that within the last two months he had examined two patients who undoubtedly had brain tumors which could not at the time be accurately localized. In each case there was astereognosis present on one side, yet when seen again the astereognosis had disappeared. These patients were examined a great many times, and it had been noted that the astereognosis was very variable, being present at one time and absent, perhaps, half an hour later.

Is Epilepsy a Functional Disease?—Dr. M. ALLEN STARR was the author of this paper. He said that he had come to the conclusion that epilepsy was an organic disease, and this opinion was based upon a personal study of two thousand cases of epilepsy of which he had satisfactory records. The recognition of Jacksonian epilepsy of several different types was now universal. This form was admitted to be a symptom of organic disease, though the nature of the latter might vary considerably. The character of the attack was uniform because the disease produced a uniform kind of irritation. In 38 per cent. of his cases of ordinary epilepsy the attack was preceded by an aura, which was identical in many cases with the sensation starting a Jacksonian attack; the only difference between a Jacksonian attack of the motor type and the idiopathic form was in the extent of the spasm. The Jacksonian attack might run into a general motor spasm, showing that there was no essential difference between the two. The same might be said of the sensory attack. In many cases the fit began with a cry, a discharge from the motor speech center. If the Jacksonian attack became severe and widespread, consciousness was apt to be lost. The close resemblance between Jacksonian and ordinary epilepsy in 23 per cent. of his cases seemed to him to offer an argument that, in these cases at least, the ordinary type of epilepsy was due to organic lesions. Another argument in support of his proposition was found in a study of cases of maldevelopment of the brain. Of 400 such cases, elsewhere analyzed, 156, or 39 per cent., were subjects of epilepsy. It was not uncommon to suppose a child to be suffering from epilepsy only, and yet careful inquiry showed a previous apoplexy. Among his two thousand cases of epilepsy, 192 showed positive signs of maldevelopment of the brain. Of his cases of epilepsy, 68 per cent. developed before twenty years of age; in other words, during the period of brain development. The speaker maintained that many cases of idiopathic epilepsy were actually cases of maldevelopment of the brain, and that the epilepsy was the manifestation of this organic disease. The incurability of epilepsy afforded another argument for the organic nature of this disease. There was no question that proper care and treatment could reduce the frequency and sometimes mitigate the severity of the attacks. He had come to the conclusion that the surgical treatment of epilepsy by exposing the brain and removing irritating foci, offered as little hope for cure as did medical treatment. He had records of about fifty cases of Jacksonian epilepsy treated by trephining, and he had yet to see a case in which such operative treatment had been followed by a permanently satisfactory result. Another argument for the organic basis of epilepsy might be found in the alleged causes of the disease. The first of these was heredity; the second in frequency was trauma of the head. That trauma of the head was a more potent cause than trauma elsewhere was well shown by the statistics of the Franco-Prussian war. These showed that out of 8,895 wounded in the head, 46 became epileptic, whereas out of 77,463 persons wounded elsewhere only 17 became epileptic. The epilepsies of advanced life could almost invariably be traced to endarteritis and atheroma. Fright was undoubtedly a cause of this disease, as 119 of his patients had the first fit after a severe fright. One great stumbling block to the adoption of the theory of the organic origin of epilepsy was the multiplicity of causes enumerated by pathologists. The epileptic attack was the symptom, not a disease. The disease was a disorder of control. It seemed to him far more reasonable to admit that epilepsy was an organic disease of the brain characterized by a lack of control of the mechanisms over motor energy. If we adopted this rule, we would more readily admit that it was incurable, and would be more willing to aid in the establishment of colonies for epileptics.

Dr. C. L. DANA said that he was surprised that the author apparently assumed that we did not believe that epilepsy was an organic disease. At least ten years ago, the speaker said, he had spoken of epilepsy as a progressive degenerative disease of the brain, but as we did not yet know always what this degeneration was, or where it was, and could not give a morphological description of the diseased cells, it was probably wise to still describe epilepsy among diseases without definite organic basis. He also doubted if the term disease was the proper one to use in connection with epilepsy. There was certainly an underlying organic degeneration, but it seemed to him that in many cases it was rather a morbid condition than a disease process—rather a teratological defect than an actual disease. So far as we knew now, it was probable that the most important factor underlying epilepsy was the tendency of large groups of nerve cells to undergo a rather progressive degenerative process. With regard to the argument about Jacksonian epilepsy, he would not say that the author's statements were not strictly correct. Some forms of Jacksonian epilepsy were as much without known organic basis as ordinary idiopathic epilepsy. He had had a case of Jacksonian epilepsy with classical convulsions confined to one arm and one side of the face, lasting for years, and after death a modern autopsy gave absolutely negative results. With regard to the incurability of epilepsy he would say that the stand taken by Starr seemed to him not only incorrect but disheartening and unfortunate. He absolutely knew of cases in which epilepsy had been cured. He knew personally of a young man who, at the age of seventeen, had nocturnal epilepsy for one or two years, the attacks coming so often as two or three times a month. He had seen the attacks himself, and they were perfectly characteristic. Under the bromide treatment this man recovered, and was now forty-five years of age, and had never had an attack since. There were now none of the interconvulsive symptoms of epilepsy, and this disease should be looked upon as cured just as much as a pneumonia might be considered cured. He had another patient who had been well for twenty years, and another for fifteen years. The very theory of the disease, assuming it to be organic, would make a cure possible. We knew perfectly well that there were certain degenerative processes that we could arrest; for example, tabes and degenerative processes affecting the kidneys or liver, for degenerative processes were not always progressive.

Dr. L. PIERCE CLARK said that Dr. Dana's statement about the curability of epilepsy had interested him, because, in an experience of ten years with epilepsy, he had records of at least two or three dozen who had remained free from epileptic attacks for periods varying from eight to twenty years. It was true that they might run eighteen or twenty years and recur again, but in such cases he would look upon them as practically cured, although the original condition might still persist. He agreed with Dr. Starr that idiopathic disease had an organic basis. He did not believe that the mere existence of an organic disease of the brain was sufficient to account even for the epilepsies of the Jacksonian type. He believed that perversions of nutrition or toxic agents were potent factors.

Dr. WILLIAM HIRSCH asked Dr. Starr for a definition of what he called organic or functional. From a strictly biological point of view, he thought, we could not make such a distinction between organic and functional. That

a disease was organic did not by any means justify us in calling it incurable. When one made a diagnosis of paranoia, one knew that it was an incurable disease, and yet it was classified all over the world as a functional disease because no one had as yet detected any organic changes in the central nervous system. The fact that Jacksonian epilepsy was frequently due to organic changes, which we recognized as such, did not prove that general epilepsy must have a change analogous to that of Jacksonian epilepsy. As Dr. Dana had pointed out, there were cases presenting quite characteristic attacks of Jacksonian epilepsy. He had in mind cases of general paresis, and particularly one case, in which death had been preceded by a very large number of these attacks, yet a careful autopsy on this patient was absolutely negative. On the other hand, there were cases of organic disease, tumors of the brain and arteriosclerosis in which epileptiform attacks never took place. We were all familiar with eclamptic attacks, attacks due to poisoning, and dependent upon transitory changes in the brain. It was manifest that all cases of epilepsy could not be said to have an organic basis.

Dr. WILLIAM H. THOMSON said that the function of a lamp was to give light, and for that purpose its structure might be a glass globe, a wick, and a reservoir of oil. If any portion of that structure were damaged it might interfere with its light-giving function, but this same function could be entirely abolished without in any way interfering with its mechanism, *i.e.* by supplying it with water or poor oil. Similarly, he conceived functional nervous diseases as truly derangements of the source of nerve function independent altogether of the structure of the brain, *i.e.* the blood. Functional disease might be so serious as to terminate life, and yet no nerve cell or fiber could be demonstrated to be diseased, the disorder perhaps having been entirely due to a toxin in the blood. He could not believe that a disease characterized so strikingly clinically by intermittency as was epilepsy could consist essentially in a structural lesion, nutritive or otherwise. He fully agreed with Dr. Starr that epilepsy was not curable by the surgeon, and, indeed, that a surgical operation upon the brain was apt to be followed by epilepsy. A polypus of the nose sometimes gave rise to an intermittent nervous trouble, asthma. He had had a number of cases in which the removal of a peripheral source of irritation had been followed by a permanent disappearance of epilepsy. With regard to the true pathology of epilepsy we were often misled in regarding epilepsy as due to a discharge in the cerebral cortex. This notion he could not reconcile with the fact that every efferent impulse was always secondary to an impulse from the afferent side. His definition of epilepsy was "a *sudden* derangement of the normal inhibition of cortical centers upon one another, dependent, in the first instance, upon an abnormal afferent impression." The majority of cases of epilepsy he believes to be the result of toxæmia. That epilepsy, with such widely varying manifestations, should be dependent upon one organic disease of the brain, he could not believe.

Dr. S. F. HALLOCK thought if we carefully investigated the psychical side in the early history of many cases of epilepsy we would obtain a strong argument for the organic origin of the disease.

Dr. JOSEPH COLLINS said that he personally felt no urgency in putting epilepsy into the camp of organic diseases, neither did he think Dr. Starr had presented any reasons for such urgency. That we might find epilepsy to be an organic disease he hoped, and he also hoped that if such discovery were made we would find the means of coping with this disease; yet Dr. Starr seemed to take a hopelessly antagonistic view on this point. Personally he had never been taught to look upon Jacksonian epilepsy as an organic disease, the point upon which Dr. Starr seemed to found his main argument. He supposed that about 25 per cent. of the cases of idiopathic epilepsy presented Jacksonian attacks, but this phenomenon he looked upon as only an indication that the irritation proceeded from a certain portion of the brain. He understood this was Hughlings Jackson's view. He knew of no organic disease which came on in the first decennium of life and continued practically for the full natural term of life; in other words, a disease that did not cut life short. He did not know of any cases of epilepsy which had been studied in the intervals of the attack except where the observations had been interferred with by medicinal treatment to such an extent as to render these observations of no value. It had been stated by several during the present discussion that changes in the brain in epilepsy had been found with a certain degree of constancy by well-recognized neuropathologists. He would say that these changes were not to be compared in any way with those which occurred in the cell bodies of the neurons in a case of poisoning by bromide of potassium, administered accidentally to a patient in Toronto a year or two ago. He thought Dr. Starr must be persuaded to modify his statement regarding the incurability of epilepsy before the publication of his paper, because it would otherwise give rise to an almost immeasurable amount of despair. He did not think there was any real justification for such pessimism. Personally, he knew that cases of epilepsy did get well, or at least practically so, and he believed we were already able to cope with epilepsy with fair success.

Dr. THOMAS PROUT said that he had studied a good deal of pathological material sent him from the Craig Colony by Dr. L. Pierce Clark. The cases dying in status epilepticus presented a uniform lesion of the cortex. In ordinary idiopathic epilepsies he found the same lesion in the cells of the cerebral cortex, but in lesser degree, and he looked upon these changes as characteristic of epilepsy. A case reported by Wright had attracted considerable attention, but this observer's methods were exceedingly faulty. The autopsy in his reported case was made fourteen hours after death and the body temperature was 108° F.

Dr. ADOLF MYER asked Dr. Starr what attitude he took concerning the fact that he founded his conclusions upon the occurrence of focal symptoms in such a large number of cases of epilepsy. What would he say with regard to the fact that the removal of such lesions failed to cure the epilepsy. The word organic as commonly used implied something far more serious than the disease as described by Dr. Starr. The persistence of the epilepsy after the removal of the organic lesion would seem to indicate that there was a general disorder present.

Dr. W. M. LESZYNSKY said that after a number of years of clinical experience he certainly disagreed with Dr. Starr in his pessimistic views as to the curability of epilepsy. It could hardly be doubted that a certain proportion of the cases of idiopathic epilepsy were cured. Reference was made to two cases in which the patients had promptly improved, and had been practically free from epileptic attacks for several years after the bromides had been discontinued, and proper attention had been given to the general health.

Dr. MAX G. SCHLAPP said that it should not be forgotten that epileptiform convulsions could be produced by many different things; hence, to take a symptom or a group of symptoms and dignify them with the title "organic disease" seemed to him to be going too far. We knew that in children convulsions could be brought on easily by slight irritation of the peripheral nervous system, and to say that these convulsions were produced by an organic lesion in the central nervous system was not justified by the transitory nature of these symptoms. The difference between a Jacksonian epilepsy and an ordinary epilepsy was perhaps to be found in the position of the lesion. If the irritation were beyond the motor center it was possible that the irritation would spread throughout the cortex, giving rise to unconsciousness and various central disturbances. The lesions described by Dr. Prout as occurring in epilepsy were found in other conditions. The principal lesions found, according to the Nissl method,

were chromatolysis, and might be present in connection with various forms of poisoning.

Dr. EDWARD D. FISHER said that he had long believed epilepsy was an organic disease. The fact that we could produce convulsions similar to what we understood as epilepsy, did not necessarily mean that they were really epileptic. The characteristic of epilepsy was its persistence; it was the general mental state as well as the convulsion which constituted epilepsy. We should sharply distinguish between idiopathic epilepsy and epilepsy due to any other non-irritating cause. He did not think Dr. Starr meant to give any definite pathology for epilepsy, but merely to state that it was an organic disease. He could not agree entirely with him, however, regarding the incurability of epilepsy, although he would admit that it probably was the most nearly incurable disease known. He could not conceive of a disease which went on year after year with exactly the same symptoms as at the beginning, without their being back of it an organic lesion.

Dr. Starr closed the discussion. He said he was exceedingly obliged to the society for its full and free discussion of this important topic. He was willing that his statements about the incurability of epilepsy should not be published; nevertheless, he believed, with Dr. Fisher, that epilepsy was one of the most incurable diseases we were called upon to treat. It was true that the various speakers had spoken of one or two recoveries, yet those present must have seen hundreds of cases of epilepsy. He thought this substantiated fully the position he had taken with regard to the general incurability of epilepsy. He had had no idea of establishing a pathology for epilepsy. He certainly regarded, and believed most neurologists regarded, the Jacksonian cases as organic. The same sources of irritation which gave rise to epileptic attacks were present constantly in other individuals, and hence, there was something else in epileptics. He believed in epileptic persons there was, in addition to the toxæmia, some underlying defect, as Dr. Dana had said. It was certainly very important to study epileptics in the intervals of the attacks, and when not under medicinal treatment; he had done this frequently, and believed it was being constantly done by others.

A Monstrous Suggestion.—A pseudo-medical journal prints some advice that would seem to call for attention from the authorities in Ohio, where *Medical Talk for the Home* is published. Apparently, the writer of the article which tells "how to produce a scar resembling vaccination" by means of nitric acid, does not believe in vaccination. He has a perfect right to his own opinion, but when he undertakes to aid in evading the regulations of health boards, the case is one for the officers of the law. "If a doctor wants to know," he says to parents, "whether the child has been vaccinated or not, simply show him the scar, and if he is satisfied with the scar, well and good." There are some added hypocritical words of admonition addressed to his fellow-physicians: "I would not advise any physician to give a certificate of vaccination after having performed this imitation, because the deception would be simply a lie, and lying is not to be approved of even to escape the necessity of being vaccinated." This wise old practitioner knows whereof he speaks. "My own children," he recalls with intense satisfaction, "have been treated in this way, and have been examined a great many times in school for vaccination, and the scars have always been regarded as genuine vaccination scars. Other children have been vaccinated in the same way, but I have always refused to grant a certificate to any one on account of this vaccination." This upright physician is too good for an uninstructed, Health-board-infested world—he should be safely shut away to think upon his extraordinary shrewdness in peace and security.—*The Evening Post.*

Therapeutic Hints.

Tuberculosis of the Epididymis.—A. H. Ferguson, in speaking of the surgical treatment of tuberculosis of the epididymis, advises its early and total extirpation; along with it the vas deferens should be removed in its entirety, and if the seminal vesicle is involved, it should be removed at the same time through the perineum. In nearly all of his cases the testicle itself was not diseased, and he believes that there are many personal and social reasons why they should be saved—*The Chicago Medical Recorder.*

Gastritis.—

℞. Menthol..... gr. ½ to 2.
Sodii bicarb..... gr. 10 to 15
M. ft. chart. No. i. S. one half hour before meals.
—CAMPBELL.

Cystitis.—

℞ Liq. potassæ..... ℥ii.
Olei santali flavi..... ♏ii.
Aquæ cinnamoni.....q. s. ad ℥viii.
M. S. ℥i. t. i. d.
—SAUNDRY.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 23, 1904:

	Cases.	Deaths.
Measles	741	23
Diphtheria and croup	395	35
Scarlet fever	427	30
Smallpox	5	1
Varicella	155	...
Tuberculosis	298	138
Typhoid fever	29	5
Cerebrospinal meningitis	...	7

Tetanus and Vaccine Virus.—This question has been studied by J. H. Huddleston, whose conclusions are as follows: (1) The fæces of calves fed on hay may contain tetanus germs. (2) Tetanus germs do not develope in glycerinated virus. (3) If any form of vaccine virus, either dry points or tubes of glycerinated virus, is infected with tetanus, it may convey it. (4) Small amounts of the tetanus infection easily fail of demonstration both by animal and by cultural tests. (5) If tetanus germs are applied in quantity to the inoculated areas of a calf at any time during the period of vaccine production the tetanus may be present in the vaccine virus collected. (6) Inoculation by scarification is a possible method of inducing tetanus in susceptible animals. (7) It is probable that precaution against the issue of infected vaccine virus consists less in tests of the virus than in care taken during production, and especially in the cleanliness of the methods in use in the stable and in the laboratory.—*Medicine.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S Marine Hospital Service, during the week ended January 23, 1904:

SMALLPOX—UNITED STATES.

SOME GROUPS OF KIDNEY DISEASE.*

BY FRANCIS DELAFIELD, M.D.,
NEW YORK.

I HAVE been asked to read a paper on the Classification and Pathology of Disease of the Kidneys. The views which I hold on these subjects, however, are sufficiently well known, so that it is hardly worth while to repeat them here.

But it has seemed to me that it might be profitable to consider the ordinary clinical groups of kidney disease and try to state as exactly as possible what our knowledge is concerning them at the present time.

1. There is a group of cases which have in common:

That the disease of the kidneys occurs in the course of some infectious disease or inflammation and is distinctly a secondary lesion.

That the urine contains small quantities of albumin and a few casts, but the excretion of urea is normal.

That the patients do not have headache, muscular contractions, dyspnœa, contraction of the arteries, or dropsy.

That if the original disease terminates in recovery, the urine becomes normal, and no kidney symptoms are developed later.

That the only change in the kidneys is a degeneration of the renal epithelium.

The diseases with which this condition of the kidneys is most frequently seen are: Typhoid fever, pneumonia, measles, cerebrospinal meningitis, measles, erysipelas, sepsis, peritonitis, and the early stages of scarlatina and diphtheria.

It is evident that, whatever we call this condition of the kidneys, it constitutes a distinct clinical and anatomical group. The prognosis of the condition is good and it requires no treatment.

While in most of the infectious diseases the kidney lesion is of the form just described, we have to distinguish five of the infectious diseases which are accompanied with kidney lesions of a different character. These are: Influenza, scarlatina, diphtheria, yellow fever, and acute yellow atrophy of the liver.

In a considerable number of cases of influenza, apparently more frequently in children than in adults, there is developed an acute exudative nephritis of varying severity.

The urine contains albumin, often in large quantities, casts, and sometimes blood; the specific gravity is not lowered. The quantity, in severe cases, is much diminished.

In the mild cases there are no symptoms except the changes in the urine. In the severe cases there may be dropsy or convulsions. As a rule the nephritis is transitory and the patients recover inside of four weeks.

These cases are not to be confounded with exacerbations of a chronic nephritis occurring in the course of an influenza.

In scarlatina and diphtheria we find three distinct forms of kidney disease. They are not different grades of the same form of inflammation varying in their severity, but from the beginning to the end of their course are separate affections.

To the first week of scarlatina and diphtheria belong simple acute degeneration of the cells of the convoluted tubules with albumin and casts in the urine, but no constitutional symptoms.

During the active period of these two diseases is the liability to an acute exudative nephritis with much albumin, many casts, sometimes blood, and a decided diminution in the quantity of urine. With this come subcutaneous dropsy and cerebral symptoms. Such a nephritis may be of severe type and prove fatal. But it regularly runs its course within four weeks, and in the patients who survive the original disease the kidneys return to their natural condition.

After scarlatina and diphtheria have run their course there may be developed a nephritis of an entirely different type. Its course is subacute, protracted, and may last for months or years.

The anatomical changes are such that the kidney can never return to its normal condition. The most marked clinical symptoms are the dropsy, the secondary anæmia and the cerebral symptoms. Albumin and casts are steadily present in the urine and the excretion of urea is gradually diminished.

With yellow fever and acute yellow atrophy of the liver there is regularly present a form of nephritis which, so far as I know, is peculiar to these two diseases.

The kidney lesion is a destructive one. Most of the epithelial cells of the kidney become necrotic and desquamate, while there is also a considerable exudation from the blood-vessels. The urine contains blood, much albumin, and many casts. There are no distinctive renal symptoms to be separated from those of the primary disease.

But the kidney lesion is so extensive that it seems as if it must have much to do in causing the death of the patient.

A very important group of cases of kidney disease consists of the cases which are either caused by or associated with chronic endocarditis.

With chronic endocarditis we find the following lesions of the kidneys: (1) Chronic congestion. (2) Chronic congestion followed by chronic exudative nephritis. (3) Chronic nephritis followed by chronic nephritis without exudation. (4) Chronic degeneration. (5) Chronic degeneration followed by chronic nephritis with exudation. (6) Chronic nephritis with exudation not preceded by congestion and not secondary to the endocarditis. (7) Chronic nephritis without exudation not preceded by congestion and not secondary to the endocarditis.

Here are seven different kidney lesions, each one of them frequently associated with cardiac disease. The diagnosis may be difficult. The general rules which we follow are these:

With chronic congestion of the kidney the cardiac symptoms are not very severe; more or less dropsy is often present; the quantity of urine is somewhat diminished, its specific gravity is normal or high, the proportion of urea to the ounce of urine is increased,

*A paper read by title at the meeting of the Medical Society of the State of New York, January 28, 1904.

albumin is present in small quantities, there are but few hyaline casts.

With chronic congestion, followed by chronic nephritis with exudation, the cardiac symptoms are more severe, there is a good deal of dropsy; the urine is scanty, its specific gravity is lowered, the proportion of urea to the ounce is diminished, the quantity of albumin is large, casts are present in considerable numbers.

With chronic congestion, followed by chronic nephritis without exudation, attacks of contraction of the arteries are of frequent occurrence; dropsy is not as constant; the quantity of the urine varies, its specific gravity is low, the proportion of urea to the ounce is diminished, there is but little albumin except when the arteries are contracted; loss of flesh and strength are marked features.

With chronic degeneration the cardiac symptoms are severe; the dropsy is moderate; the quantity of the urine varies, its specific gravity is unchanged, there is but little albumin. The patients are feeble and anæmic, they die with a prolonged period of scanty urine, delirium, stupor, and the typhoid state.

With chronic degeneration, followed by chronic exudative nephritis, the cardiac symptoms are severe and the dropsy well marked. The quantity of urine is small, its specific gravity is rather high than low. Albumin is present in large quantities, casts are not as constant. The patients are feeble, anæmic, and get worse rapidly.

With chronic nephritis, either with or without exudation, not preceded by congestion, there is the ordinary history of chronic nephritis lasting for months or years. Then at some time a stenosis of the valves becomes tighter, an insufficiency becomes greater, the heart's action fails, the circulation is inefficiently carried on, and cardiac symptoms are added to those of the nephritis.

During the later months of pregnancy, during labor, and immediately after childbirth, women not infrequently become anæmic and dropsical, have albumin in the urine and develop cerebral symptoms —headache, blindness, convulsions, and coma. The cases vary in their severity.

1. There are a considerable number of women in whose urine during the latter months of pregnancy albumin is present in appreciable quantities. They have no other symptoms and pass through labor without trouble.

2. There are women who, during the later months of pregnancy, have scanty and albuminous urine, more or less dropsy of the legs and a secondary anæmia. They may pass through childbirth safely and do well afterward, but some of them go on to have a chronic nephritis dating from the pregnancy.

3. In a small number of women at or about the time of childbirth, either before, during or after labor, there are cerebral symptoms. In some of these women albumin has been present in the urine during the pregnancy; in others, besides the albuminuria, dropsy and anæmia have also been present; but in others the cerebral symptoms are suddenly developed without any premonitory conditions.

The cerebral attacks are characterized by nausea and vomiting, headache, blindness, muscular twitchings, general convulsions, stupor, coma, hemiplegia, a rise of temperature, a pulse of high tension, venous congestion of the skin, the urine diminished and suppressed.

The cases vary as to how many of these symptoms are present.

In the fatal cases death takes place with the convulsions, coma, or hemiplegia.

Of the patients some go on for the rest of their lives without the slightest evidence of kidney disease, others on the contrary after a time develop the symptoms of chronic nephritis.

One would rather expect that in all these cases we would find one form of kidney lesion varying only in greater or lesser development. This, however, is not the case. A number of different kidney lesions have been described.

In my own experience in women dying with cerebral symptoms and albuminuria at about the time of childbirth, I have found the kidneys in the following conditions: Normal kidneys, dilatation of the pelves and ureters, acute degeneration of the kidneys, acute exudative nephritis, acute productive nephritis, chronic nephritis.

In some of the patients, even in young women, I have found well-marked disease of the cerebral arteries.

There is a group of cases which has interested me a good deal—that of young persons, boys and girls, who have albumin and casts in the urine with anæmia and no other symptoms. This group may be divided as follows:

1. The ordinary cases of simple anæmia in young women with albumin and casts in the urine. These are of ordinary occurrence, the patients only need the routine iron treatment, the morbid condition of the kidneys is transitory and unimportant.

2. There are cases which behave as if they had a mild exudative nephritis. The patients are hardly sick enough to go to bed. They have a little headache, perhaps some aching in the back and limbs, loss of appetite, a little nausea, and the feeling of general malaise. They often think that they have taken cold. It is possible that some of them are cases of influenza. These indefinite symptoms last for one or two weeks, disappear, and the patient is well again. If the urine is not examined it is not known that the patient has been suffering from a mild nephritis. If the urine is examined, it is found that the quantity is somewhat diminished the specific gravity is not lowered, an appreciable quantity of albumin is present with hyaline, granular and epithelial casts, sometimes with blood. These changes in the urine last for four or five weeks, sometimes longer, and then disappear. The patients hardly require treatment and recover completely.

3. There are young persons who, for months or years, have a little albumin and a few casts in the urine with a moderate secondary anæmia. It is very difficult to tell whether or no they have a true nephritis. As a rule they get entirely well.

The great secret in managing them is to give them plenty to eat and out-of-door exercise. Iron is not of much service.

4. The cases of so-called cyclic albuminuria, the albumin present in the evening after exercise and absent in the morning after rest have been sufficiently described. The general rules for their management are pretty well agreed on.

There is a group of cases of primary nephritis which run a subacute course from the outset. We call them primary because they occur without discoverable cause in persons whose health has previously been good. The condition is especially common in young persons between the ages of twelve and twenty, but it is also seen in older persons.

In some persons at first there are only loss of appetite, headaches, and an increasing pallor of the skin and mucous membrane.

In some persons dropsy of the face and legs and anæmia are at first and for a considerable time the only symptoms. They continue to eat well, feel

well, and attend to their work. It is hard to realize that they are beginning a serious illness.

In many of the patients dropsy of the legs and face, anæmia, headache, sleeplessness, loss of appetite, nausea, and vomiting are developed at about the same time.

The urine is moderately diminished in quantity, there is a large quantity of albumin, a considerable number of casts, sometimes blood. The specific gravity remains normal, or falls a little.

The course of the disease varies:

1. The patients are sick for several weeks with one or more of the regular symptoms: albumin and casts in the urine, anæmia, dropsy, headache, and disturbances of digestion. The attack runs its course, the patients get well, with damaged kidneys. They do not continue to have a nephritis, but they have kidneys which are susceptible to fresh attacks of inflammation. Sooner or later, it may not be until after several years, they are apt to develop a chronic nephritis.

2. The patients begin in the same way with an attack which lasts for several weeks. Then the symptoms subside, but the nephritis continues, a very slow chronic process with few symptoms, but a gradual fall in the specific gravity of the urine, with the presence of small quantities of albumin. The patients may live in this way for many years in comparative health, but they are not really well, and in children the development of the body is seriously interfered with. It is possible for these patients to recover, but they are apt to die with an exacerbation of the nephritis, or in the condition of chronic uræmia.

3. The first attack is succeeded by other attacks, which follow each other at intervals of weeks or months. Between the attacks the patients are comparatively well. But each attack is worse than the preceding one, and finally there comes an attack which proves fatal.

4. The most distressing cases are those which are severe and continuous. The patients steadily get worse, and yet months may elapse before their sufferings are terminated by death. The color of their skin and mucous membrane becomes more and more white; headaches are constant and troublesome; sleep is difficult and unrefreshing; the eyesight is impaired or lost altogether; there is no appetite, but rather constant nausea and irritability of the stomach; from time to time the arteries are contracted, and there is a disposition of muscular twitchings and general convulsions. The dropsy constantly increases, no matter how large the excretion of urine. The subcutaneous connective tissue is everywhere œdematous and the serous cavities contain more or less serum.

Not only does treatment fail to control the nephritis, but we are unable even to alleviate the symptoms.

The majority of these cases, especially in hospital practice, terminate unfavorably. Either the disease goes on continuously and the patients die at the end of a few months, or the acute symptoms subside and a chronic nephritis supervenes.

But it does not do to forget the favorable cases. Some patients live for many years in very fair health, some seem to recover altogether.

To Cleanse Hypodermic Needles.—If neglected so that the wire cannot be passed, the point may be heated in an alcohol flame to turn out the organic matter. When the wire is rusted in the cannula, the latter should be allowed to soak overnight in neutral oil, and then heated as before. After that, all traces of rust are removed by forcing into the point more oil.—*Medical Times and Hospital Gazette.*

SOME MODERN VIEWS OF GASTROINTESTINAL TROUBLES AND THEIR TREATMENT BY MASSAGE.

By GUSTAF NORSTRÖM, M.D. (of the faculty of Stockholm), New York.

Several years ago, shortly after my arrival from France, I published in the Medical Record a short article on the "Technique of Massage of the Stomach." This article dealt chiefly with the technical part of the subject. I now purpose to discuss particularly the clinical results of massage of the stomach, based on my experience with it, and to show the relation which exists between the general improvement that has followed its use and the chemical activity of the stomach. This will be followed by a brief article on manual massage of the bowels.

In a number of cases referred to, suffering from gastric indigestion, the gastric juice was analyzed from time to time. We have been able to compare the changes in its composition, and observed that there has been a uniform improvement in the chemical action of the stomach, corresponding to the gradual improvement of the patient. This procedure is not a new one. It has been practised in an empirical way by those in whose hands it was often prejudicial to the patients, and, further, its best results were not obtained.

The beneficial results of massage of the stomach were first set forth by Rubens Hirschberg in his interesting article on "Massage of the Abdomen," which was soon followed by Dr. Cautru in a well-written thesis entitled, "De l'Emploi des Agents Physiques et en particulier du Massage dans le Traitement des dyspepsies," in which he relates the results obtained with its use at the Hôpital St. Antoine (Clinic of Professor Hayem), together with his subsequent results at the Hôpital Necker (Clinic of Professor Huchard). My friend, Professor Zabludowski in Berlin,* Cseri,† Schmidt and others have also written articles on the subject. It is besides a well-known fact that Dr. Metzger, the father of scientific massage, whose methods I am endeavoring to introduce into this country, long ago employed this adaptation of massage, not only in the treatment of local affections of the stomach, but even in systemic conditions, which he thinks result from faulty stomach digestion (gout, etc.). I hasten to say right here that the kind of massage I am advocating in this article for gastrointestinal troubles, differs, particularly in its application in the gastric disorders, a great deal from the methods employed thus far by others and by myself up to about fourteen years ago.

As this one yielded in my hands quite unsatisfactory results, I gave up massage entirely in the first-named disorders for two years. It was at that moment I devised the method I have employed ever since, and which has yielded often the most splendid results, the manipulations, etc., of which I shall describe later on.

The numerous drugs usually employed in the treatment of gastric indigestion, as well as any treatment applied thus far, were dispensed with soon after a course of massage was begun, and then the only treatment employed was the physical agent massage.

We will now briefly discuss what might be termed the chemical disorders of the stomach, as to discuss the subject in a comprehensive manner as I should like, would unduly lengthen the article.

It can readily be assured without further reason-

* *Berliner klinische Wochenschrift*, No. 26, and following.
† *Wiener medizinische Wochenschrift*, 1889, "Die Mekanische Behandlung des Magens."

ing that in that clinical trouble of the stomach that we call *Hypo-chlorhydria* (Hypopepsia-Hayem),* (Hyposthénie—A. Robin), in which, as it is generally known, there is deficiency not only of the gastric juice but at the same time of free hydrochloric acid, the physical agent massage could remedy both conditions. We know that direct or indirect excitation of the stomach immediately provokes a flow of gastric juice through reflex action. This stimulating effect of massage on the glandular function was first demonstrated by Dr. Colombo, formerly of Turin, now of Rome, who employed massage upon dogs, in which he had first made gastric fistulæ. From these experiments he concluded that massage acts upon the glands through a double action, on the one hand stimulating the glandular epithelium and on the other determining an increase in the blood supply to the organ which favors the secretion. In addition to this special action on the glands the secretion is also increased by the peristaltic movements provoked by massage.

I have long taught that massage of the stomach improved the quality of the gastric-juice secretion. A number of others, and particularly Rubens Hirschberg, have followed me in this. But Dr. Cautru (*vid.* thesis) was beyond all question the first to demonstrate scientifically that it also acted in this way.

We must not, however, forget that during digestion two phenomena are taking place: one of them vascular, characterized by increased determination of blood, and the other glandular, by which the chlorides of the blood are decomposed into hydrochloric acid and organic chlorides. In France the name of *chlorhydrie* has been given to the first of these phenomena, and it should be directly proportionate to the amount of chlorides required in the organic chlorides. There should also be a proper proportion between these two phenomena during the whole of digestion, and the various stages of the process ought to take place according to certain rules which maintain this equilibrium.

In order to determine the influence of massage upon the digestion, it appears to me almost indispensable to compare the analysis of the gastric juice on the same individual at different stages of the treatment of both varieties of disturbance of the gastric juice.†

When there is hypochlorhydria, in which there is a diminished chemical action and corresponds to to the formula — HCl, as a result of massage there is hastening of digestion due to an increase of the quality of hydrochloric acid. Glandular action is more active, Cl having increased and osmosis proceeding more rapidly.

The establishment of better gastric digestion through massage is shown by increased appetite and greater rapidity of digestion, the first of which is generally the first sign of approaching improvement in the massage of any disease of the stomach and which causes great rejoicing to the patient.

CASE I.—*Hypochlorhydria — Chronic Gastritis—Atony of the Stomach—Nervousness.* Mrs. S., thirty-seven years of age, came for treatment August, 1895. Treated at first for a fortnight in Europe with slight improvement. Seen again in October in Brooklyn. Was extremely emaciated, having lost about fifty pounds and unable to digest any kind of food. Since 1891 suffered from pain and eructions; cramp in the region of pylorus. Stomach washed out for seven months without relief. Operation refused. Very nervous and was believed to have a functional disease; obstinate constipation. Treatment lasted for six weeks (in this country); could digest anything (plum pudding). Stomach normal. No more pain resp. cramp; constipation gone. Gained thirty pounds in ten months. Perfectly healthy at present time; has gotten stout.

CASE II.—*Hypochlorhydria—Chronic Gastritis—Atony.* Mr. W., sixty-one years of age, complained for thirty years of stomach trouble. Suffered also last three years from chronic diarrhœa; very weak; acid eructations and gases. Since ten years could not digest meat; his diet was milk, eggs, oysters, and meat juice. Very much emaciated. Hypochlorhydria. After five weeks' massage, notable improvement. After nine, perfectly well; diarrhœa gone. His tongue, which had been thickly coated for many years, gradually cleaned off from edges to middle line as improvement progressed. Gained in four to five months twenty-four pounds in weight. Can digest anything. Gastric juice normal. Three years after massage perfectly well. Bowels regular.

CASE III.—*Chronic Gastritis—Atony of the Stomach.* Mr. O. referred to me by Dr. Keys in 1896. Condition bad, face sallow, looked like a very weak man. Has been suffering for at least four years. Got worse through drugs. Could hardly stand any food, not even milk; acid eructations in great quantities; vomiting at times. Vomited matters examined showed hypochlorhydria and a great deal of mucus. On account of his bad condition looked like a man having cancer. I was afraid to massage him. Proposed three weeks' massage; improvement; continued massage five to six weeks. Acid eructations highly improved; no more belching. Can now digest as well as before his illness. Gastric juice normal; very little mucus left. Has enjoyed perfect health, as concerns his stomach, since that time.

When, on the contrary, we have to do with the other variety of disturbance in the chemismus of the stomach named *Hyperchlorhydria* (*Hyperpepsia*—Hayem; *Hyperesthénie*—A. Robin) there is increased acidity, which irritates the gastric mucous membrane; it has, as a general character, + HCl—that is to say, increase in the hydrochloric acid in a free state.

After massage is employed there is generally a regulation of the chemical action, and the different factors approach the normal conditions.

In addition to the plethoric, congestive hyperchlorhydria, to which I would prefer to give the name *true* hyperchlorhydria, Cautru admits a second form, to which he gives the name *false* hyperchlorhydria. I have encountered a certain number of these, which, while giving all the symptoms of hyperchlorhydria (burning acid eructations, sudden feeling of hunger), are found in each by an analysis of the gastric juice to be hypochlorhydria with secondary fermentations. Massage gives good results in both varieties, but particularly in the latter, as might be supposed. Further, the condition is cured in much shorter time.

The indication for massage in the disease in question has not generally been recognized by the profession, and many who admit its usefulness in cases of hypochlorhydria, are rather skeptical of any good results in the latter condition. Dr. Cautru, whose name we have so often quoted, has had quite satisfactory results in its use in the latter affection. I see with pleasure that these results have been confirmed by Professor Huchard, at whose clinic in the Necker Hospital, in Paris, most of the cases have been

*"Chemisme stomacal," Hayem-Winter, Paris, 1892.

† I purposely omit here anachlorhydria, as this is a rather rare disorder of the stomachic chemism.

treated.* On perusing the voluminous and excellent work on gastric disorders by Prof. Alb. Robin,† I learned that he, from personal experience, expressed himself in favor of massage applied to the digestive organs, but excepts hyperchlorhydria, as he always has found the secretion increased after massaging. On account of this, I addressed a letter to him, which he kindly inserted in his journal (*Bulletin Général de Thérapeutique*, May, 1903). I tried in this to explain why he has not obtained the same results as Dr. Cautru and myself in these cases. The real cause of Dr. Robin's failure, I think, is due to the fact that he has not persisted sufficiently long in his treatment. I have always noticed that in massaging cases of hyperchlorhydria there is an increase of the gastric juice during first few weeks, and only after five to six weeks the regulation of the glandular function takes place as a result of the treatment. I would be pleased if, after this explanation of my experience, Dr. Robin would again take up the treatment in the proper cases. I am assured that, if he will do so and apply massage as I do, he would modify his ideas.

Owing to these facts one would readily conclude that the time required for the cure of hyperchlorhydria would be longer than that required for hypochlorhydria. Three months are sometimes required, during which the patience of both physician and patient are often sorely tried.

The treatment of hyperchlorhydria is still more obstinate, when there are complications on the part of the nervous system, and the results are then generally not very good and relapses occur most frequently.

It seems strange that massage, at first stimulating the secretion of the gastric juice, should end by reëstablishing its normal quantity. But this same apparently paradoxical condition is formed, as I shall speak of later on, in the treatment of constipation and diarrhœa by massage, which acts upon the nerves of the stomach, the circulation of its walls, and consequently upon the whole nutrition of the organ, including that of the glands, and reëstablishing in this way the normal anatomical and physiological conditions.

Case IV.—*Hyperchlorhydria—Dilatation of the Stomach—Diarrhœa.*—Mr. K., forty-four years of age, came to me in 1893. Stomach trouble for six years. Strong fermentation in stomach and bowels. Diarrhœa for ten months. Burning of "hot water" after every meal. Sharp pain three hours later. Woke up every morning at five from pain (acidity). Complains of eructations. Some relief from washings. Slight transitory relief, too, from NaBi. Gastroenterostomy proposed. Refused. Test-meal (Riegel). Débris and hyperchlorhydria. Irritation of the bladder due to reflex from the stomach trouble. After treatment gone. Condition now quite healthy; no débris. Reaction almost normal. No more diarrhœa. Treatment lasted almost eleven weeks.

Case V.—*Hyperchlorhydria—Violent Cramp of the Pylorus.* Mr. K., forty-six years old, composer of music, suffers since 1873 from stomach troubles. Every year a season at Vichy; some relief for five or six weeks. End of 1888 exceedingly violent attacks of pain; had their seat in the region of pylorus; radiating upward but especially downward; on this account he was believed by physicians to be suffering from hepatic colic. The attacks came on with predilection in the evening after the principal meal; complained of burning sensation right after meals, but particularly two to three hours after it. At this latter time the cramp was especially violent. Belching up of very acid gases. Bicarbonate of soda in large quantities with only transitory effect.

The stomach often refused to digest anything, in spite of a strict and especially monotonous diet. Got thin and easily tired; could not work for any length of time. Obstinate constipation. Hyperchlorhydria. Treatment by massage for nine weeks, started in the beginning of October, 1893. In the middle of the treatment a violent attack, but up to May, 1895, when I saw him last in Paris, he has not had any relapse. Patient eats everything without complaining of any pain in the stomach. Constipation entirely gone after a particular application of massage.

There exists another affection—more a complex of symptoms of a certain nature than a real disease *sui generis*—named *Reichmann's disease*, and which resembles hyperchlorhydria very markedly, more perhaps in regard to its symptoms than to its etiology. I have no experience as regards the propriety of application of massage in this not very frequent gastric disorder, but concluding from the results massage yields in hyperchlorhydria, and from the same cause, as I am going to show, it seems to me rational and worth while to try it in proper cases. That is particularly the case when there is—what seems to happen rather often—atonic condition of the walls of the stomach coexisting.

Its use is, of course, contraindicated when an ulcus is the causative factor of the affection in question, and this may sometimes happen according to Strauss* and others, without agreeing with Hayem and his school that ulcus ventriculi, "en activité," or in a state of healing up, is always the existing cause in the continuous secretion of the gastric juice.

To sum up, massage influences the glandular elements of the stomach, modifying the chemical action.

1. It tends to approach the relations expressed in the formula to the normal relations.

2. It reëstablishes the equilibrium in the components of the gastric juice, lowering them when excessive; raising them when deficient.

3. It acts particularly upon the "evolutif" troubles, in increasing and regularizing in a constant and manifest manner the evolution of digestion.

The treatment of the dyspepsias, complicated or not, ought to aim to restore the chemical equilibrium, as well as the physiological functions. In order to arrive at this, a strict régime is not always sufficient. It is besides necessary to reduce medication, which is far more harmful than beneficial here, to a minimum, and employ those agents which will reëstablish the equilibrium interrupted, and supply by natural means the physiological agents lacking.

With many others, I hold the view that a great many diseases of the stomach, and especially chronic gastritis and nervous dyspepsia, when the analysis of the gastric juice shows some abnormality, the disease itself remains for a longer or shorter time in a latent state, until the mobility of the stomach begins to suffer. This brings out the symptoms and makes the patient complain of a malady of which he has, up to that time, been an unconscious victim. Whereas, if the motor element

* "Consultations Médicales," Paris, 1901.

† "Maladies de l'Estomac," Paris, 1876, 3 volumes.

* "Klin. Studien des Magensaftflusses," *Mittheilungen aus den Grensgebieten der Medizin und Chirurgie*, 12 Bd. 1 H.

is intact, the abnormal condition of the gastric juice is overcome.*

The condition of hyperchlorhydria is an exception to this rule, although even here we sometimes notice how a rather large excess of chloric acid may exist without the patient complaining of any pain, the latter depending upon the higher or lesser degree of sensitiveness of the mucous membrane and its different reaction against the increased acidity. But even in these cases we observe how the above-mentioned rule is prevailing; the patient starts to suffer as soon as an atonic condition—a state more frequent in my opinion than is generally admitted—is added to the pre-existing one.†

How then may we be able to explain that not only the amyloids but also the albuminoids could be digested, absorbed, and benefit the organism under the most unfavorable conditions of chemical action of the stomach? It is because it has been demonstrated in the most positive way that the pancreatic juice may act as a substitute for the gastric juice‡ and digest any animal food. This would formerly have seemed paradoxical.

*Having perused the literature on troubles of the digestive organs, I notice with pleasure how many specialists of diseases of the stomach—and among them, particularly those of German nationality, and at the head of them the leading specialist, Dr. Boas ("Diagnostik und Therapie der Magenkrankheiten," Berlin, 1901), are getting more and more disposed to recognize that the motor element plays the most important part in the digestive act—what was, until a few years ago, almost neglected. But I am particularly satisfied in observing how, even among the French specialists, this opinion seems at this moment to predominate. Thus, for instance, such an eminent specialist as A. Mathien expresses similar views in an article published some months ago in the *Gasette des Hôpitaux*, when he says: . . . "We have arrived at attributing to the condition of mobility and sensitiveness of the stomach a preponderant value in dyspeptic troubles."

†It has been generally admitted that in hyperchlorhydria the peptonization of the albuminoids is accelerated through the excess of chloric acid secreted, and, moreover, that the albuminoids, owing to this circumstance, leave the stomach sooner than usually. But this last view has been upset by Pawlow (Das Experiment als zeitgemässe und einheitliche Methode mediziner Forschung, Wiesbaden, 1900), as have also been so many others which have prevailed thus far, in the field of gastric physiology and pathology.

By his remarkable experiments it has been shown that the question of passage of the contents of the stomach into the duodenum is regulated by nothing less than the chemical reaction of the duodenal ingesta. A portion of the acid contents of the stomach through reflex action from the mucous membrane of the duodenum provokes a temporary closing up of the pylorus.

At first, when above-mentioned acid mass has been neutralized by the alkaline pancreatic juice, the pylorus opens up and another acid portion is allowed to pass into the bowel.

From this it is clear that the hyperacid ingesta of the stomach ought to take longer time to leave the latter than those of normal composition, and that, consequently, the transformation of the acid stomach-digestion into the alkaline pancreatic one ought to be to a certain degree more difficult and retarded.

The stagnation of ingesta in hyperchlorhydria is, moreover, frequently increased by the reflex cramp of the pylorus that impedes the exit of the sour contents from the stomach.

It really seems as if these retarding elements in the stomachical digestion would not be a matter of chance, as nature, owing to a marvellous disposition here as well as in other gastric troubles, would do its utmost in order to keep up the digestive equilibrium. Otherwise a portion of the very acid gastric contents—the albuminoids being easily, as I have mentioned, peptonized under influence of hydrochloric acid secreted in excess—could leave the stomach too soon, and then a disorder in the digestion could take place.

‡ Those who may be interested in the further study of the most important functions of the pancreas, are referred to the very interesting and epoch-making discoveries of Pawlow, described in his work, "Arbeit der Verdauungsdrüsen," Wiesbaden, 1898 (also in French.)

The action of massage upon the gastric muscle is very evident, and when the abdominal walls are very thin, peristaltic and antiperistaltic movements may sometimes be observed. Its action has been demonstrated by numerous experiments; among others, those of Rubens Hirschberg, who has shown, for instance, that two eggs remain in the stomach four hours and fifteen minutes. After massage of the stomach for ten minutes they remained only two hours and forty-five minutes. Besides 300 gm. of roast meat five hours and thirty-five minutes; after ten minutes massage, three hours and thirty minutes. The same author stated that if two hours and thirty minutes are necessary after administration of salol, before it appeared in the urine as salicyluric acid, after fifteen minutes of massage it will appear in an hour and a half.

Motor insufficiency begins almost always in the shape of an atonic condition of the muscular wall, pathological-anatomical changes being absolutely lacking, and manifests itself only in weakness of the named wall and a tendency of yielding to the pressure of the stomachical contents. This condition may remain as such—and this happens most frequently—or it will, if the etiological conditions persist, gradually turn over ino a real dilatation, on account of fatty degeneration or some other pathological alteration, probably setting in in the tunica dartos.*

In this event the stomach will be unable to empty its contents at the proper time. But it will eventually do so with pain and the digestive process prolonged (atony), or the stomach will only be able to get rid of only a portion of its contents itself, and a greater or less quantity of indigested food will remain when the stomach ought to be empty (dilatation). In the former condition massage often has a wonderful effect, the contractile power of the stomach being entirely recovered; while in the latter, even if a restitutio ad integrum may not occur from an anatomical standpoint, the patient's condition is improved to such an extent that one may almost speak of a cure, the patient scarcely complaining of any symptoms at the end of the course of massage, and no symptoms returning, at least not for a number of years.†

When I first came to this country I treated a number of cases of this kind with great success, which had been unsuccessfully treated by other methods and who came to massage as a last resort, before undergoing a proposed gastroenterostomy. The condition of these was most deplorable; the patients having given up a great many articles of food. In some there was also chronic diarrhœa and they were extremely emaciated. In such cases the treatment required will take much longer, as can easily be surmised—three months being occasionally required for a certain cure.

I have alluded to the fact that the gastric juice is not, as it is commonly believed, necessary for the digestion of albuminoids. Experiments upon animals have certainly demonstrated this, although little was made of this fact. It was alleged that conclusions derived from experiments upon animals did not necessarily apply to man. Dr. Schlatter of Zürich demonstrated, however, in a case of extensive cancer of the stomach, in which total extirpation was

*I hold the same view as Nothnagel and many others that primary dilatation of the stomach is a relatively rare affection, the presence of which has, in my opinion, been highly exaggerated, particularly in France, where, for a rather long time, under the influence of the doctrine of Bouchard, there was almost no case of stomach trouble in which the diagnosis of primary dilatation had not been made.

†We speak here only of idiopathic dilatation, as the one produced by stricture of the pylorus is, of course, not susceptible to our treatment

performed, that the above statement also applied to men. The patient in question was a woman advanced in years. She could digest meat as well after the operation as before, when she was still in possession of a healthy stomach. It is, of course, self-evident that the food had to be administered in small portions and at frequent intervals.

Under this régime she was doing well and had gained four pounds in weight at the end of one year. Two months later this patient succumbed to a disease which did not have the slightest relation to the above condition, namely, to a recurrence of the cancer in the mesenteric glands.

What I have just stated about the non-necessity of the gastric juice for the digestion of albuminoids applies only to stomachs in which the motor power is preserved. However, as soon as the latter begins to suffer, which may happen in any disease of the stomach, the patient begins to complain. The food remains too long in the stomach. It undergoes fermentation, and its walls are being distended by accumulation of gases. Under these conditions the stomach finishes by contracting, the resistance of the pylorus is overcome, and its contents are driven out into the duodenum, the reaction of the food being excessively acid. The alkaline pancreatic juice can neutralize only a part of the contents and the digestion will consequently be incomplete.

If proper massage is applied to the walls of the stomach, the latter will recover their contratile power, the stomach contents, solid as well as liquid,* will remain in the stomach no longer than usually, and decomposition is thus prevented. The food is expelled at the proper time into the duodenum, where it will be digested by the pancreatic juice independently of its chemical reaction.

I have not found it convenient to describe massage in its clinical applications in the different forms of gastric affections. In those which are characterized by what the French call "ralentissement de la digestion"—chronic gastritis, idiopathic dilatation of the stomach, nervous dyspepsia—particularly in the first and the last, different chemical conditions are observed at different times, being produced probably by some particular nervous influence, and from time to time it happens that these conditions change, and sometimes in a very short time, from one extreme through the normal to quite the opposite.

I think, however, I may here make an exception of nervous dyspepsia and gastralgia, as in both these affections we have to do with a nervous element as primary or secondary cause of the disease. The treatment we are discussing is not applicable to the first of these diseases, as I believe in the great majority of cases this affection is dependent upon a systemic condition and is only to be regarded as one of the many manifestations of neurasthenia and hysteria. These ought then to be treated, and not the stomach trouble itself. However, everybody who occupies himself with diseases of the stomach will agree with me in recognizing in some cases the difficulty if not impossibility, at a certain degree of development of the disease, in differentiating the two conditions, and determining whether the gastric trouble is the initial factor, the primary and most important affection, susceptible to our treatment, or secondary to the systemic condition.

It is in these doubtful cases, in which instead of the local disease I regarded and also treated a symptom, that I have failed with my treatment. Still, even in these cases massage of the stomach and bowels has at times yielded favorable results, although only temporarily. A few months after the treatment was stopped a relapse would occur, the time of improvement never exceeding one year.

How can we explain the effect of massage in such cases? I believe that massage stimulating the appetite, a lack of which these patients often complain of, the patients eat more at the same time, as the digestion is improved. This acts as a great tonic upon the general condition of the patient as well as upon the nervous system, while the latter acts favorably back upon the stomach and intestines.

Gastralgia may be divided in two classes: Idiopathic gastralgia, and gastralgia dependent upon a general cause, such as chlorosis, neurasthenia, and hysteria. These last conditions, although sometimes benefited by massage, disappear only when by appropriate means the exciting cause has been removed; all the more, when there is an organic substratum as tabes dorsalis as its cause. In regard to the idiopathic form, we have rarely seen it not to respond to treatment by massage, and strange to say, after but very short treatment the patient frequently experiences relief, as is often the case in neuralgias in other parts of the body. Among others, I may cite the case of a young lady in Paris, who had suffered for a certain number of years from violent gastralgia and who was cured after only three weeks of massage. I saw her two years later, and no relapse, what I have sometimes seen, in similar cases, had occurred.

One might *a priori* suppose that in the *Gastroptose* massage would yield the most satisfactory results; but I am sorry to say that in my experience, no matter how long you apply massage, the results are entirely negative as concerns the abnormal position of the stomach, which will remain absolutely the same after as before this treatment is employed.

We frequently notice, however, cases which are due to a general constitutional cause—as well as cases following a post-puerperal condition and due to an increasing of the abdominal cavity through relaxation of the abdominal walls—in which the gastric displacement does not give rise to any symptom by itself; the patient completely ignoring that he is a bearer of the abnormality in question, which is then only discovered by chance. It would certainly be the same in some cases of gastroptose, in which a local agent is found to be the causative factor, were not the motor element most often more or less lacking in its functions. Yes, motor insufficiency is here in reality not only frequently complicating the abnormal position of the stomach, we are speaking of, but in the second variety it is, at least in the great majority of cases, also the real origin of it, the stomach overcharged by stagnant ingesta yielding to its increased weight and consequently gradually sinking down.*

It is in trying to act by our treatment upon this atonic condition we are often able to bring the patient to such a state that he does not longer complain of any trouble.

Absolute contraindications to massage of the

*According to the experiences of Dr. von Mehring on dogs, water is absorbed in but small quantities in the stomach. This is contrary to what was formerly supposed. Half to three-quarters of an hour after its ingestion the water has entirely entered the duodenum where it it absorbed. (Moritz).

*The motor insufficiency, as a consequence of gastroptose seems, on the contrary, to be a rather rare complication, although theoretically one might suppose that the contrary condition would take place, the pars descendens duodeni remaining fixed, owing to its insertion to the back of the abdominal wall, and the stomach descending, the distance between the lower border of the stomach and the antrum pylori would thus be increased. The food would consequently meet more difficulty in leaving the stomach; the latter would be obliged to make more efforts and contract more energetically in order to empty its contents.

stomach are chronic ulcer and cancer. In regard to massage of the stomach in the former of these it would not only be useless, but dangerous too, as it might give rise to hemorrhage. But the same objection might be raised to the treatment of any gastric affection by internal physical means, the washing out of stomach contents not being excluded.

We have, however, since a short time a means at our disposal in discovering an ulcus ventriculi, namely Mendel's hammer. I consider the latter a great discovery and of very great practical importance, because it enables us to exclude ulcer of the stomach and even of the duodenum in doubtful cases.*

In the incipient stage of infiltration of cancer in the walls of the stomach, when this has not yet given rise to a tumor, an error in the diagnosis can easily be possible, and indeed† has certainly often been made.

But I don't think that three weeks' massage during the initial stage could do any harm. I say three weeks, because after that time I generally notice an improvement, no matter how slight, in all stomach affections in which massage is applicable.‡ If we had to deal with cancer of the stomach, no improvement could of course be expected, and the treatment would be stopped.

I would now say a few words about the *technique* of massage in the affections we have to deal with.

I consider that the remarkable results obtained in the treatment of the digestive organs by massage are greatly due to the position occupied by the patient during the sitting. Up to the present time massage of the stomach was practised with the patient in a position on his back. In this position the operator could only employ frictions, and nothing but frictions, upon the anterior wall of the stomach. And these were, moreover, more or less incomplete, because the stomach, carried down by its own weight, fell backward and became consequently more or less inaccessible to the operator, who was unable to perform the proper manipulations. For the last fourteen years I have discarded this method of procedure and have employed at first the right lateral position and then the left one during the same séance. This method possesses the great advantage of causing the stomach to fall forward and at the same time toward the corresponding side. The stomach is even seen to be bulging out and thus becomes readily accessible to the operator's hands. This position has, moreover, the advantage of allowing the operator to sit with perfect ease at the side of the patient and perform massage, whereas if the patient is in the other position, the operator is obliged to stand upright, which is very fatiguing and a great strain to his back.*

The hands grasp now a large segment of the wall of the stomach and the thumb of the right hand is forced as deep down as possible. Real energetic pétrissage is now practised, the object of the treatment being not to act only upon the glands, nerves, and muscular fibers of the stomach, but also upon the arterial, venous, and lymphatic circulation. Massage will also aid in bringing the contents of the stomach into intimate contact with the secretions.

I have stated above that massage must be practised with a great deal of strength. In hyperæsthesia of the abdomen or stomach walls, however, massage has to be performed gently; the pressure may be increased gradually, not only during the same séance, but also in subsequent séances, when the sensitiveness diminishes owing to massage. The secret of success is to possess a strong thumb and know how to massage. These are two requisites in scientific or Metzger's massage in other diseases, but they are especially requisite in massaging the stomach and the bowels. Without them you cannot penetrate sufficiently deep and know exactly what you are doing.

What is the best time to perform massage? The answer is in the morning when the stomach is more or less empty, or in the afternoon, a few hours after the mid-day meal.† The length of the séance is usually 15 minutes.

The question has arisen if massage, performed during digestion, would not interfere with this physiological process. The experiments of Rubens Hirschberg, as I have mentioned, as well as those of Gopadze, and particularly those of Dr. Beulet of Berne (*Correspondens-Blatt für Schweizer Ärzte*, March, 1888), have clearly demonstrated, however, that massage stimulates the peristaltic movements and increases the amount of the gastric juice secreted through excitation of the glands. This favors better digestion and consequently the quantity of fæces is diminished. This latter may be great enough to frighten some patients.

Manual massage of the bowels for the cure of *constipation* has been employed for a long time. It is only of late that an attempt has been made to replace the human hand by different mechanical devices, such as the rolling disks of Zander's apparatus or rolling large, heavy metal balls in different directions over the whole abdomen (method of Sahli). These mechanics, as well as manual treatment, as practised by the ordinary masseur or masseuse in this country, have very frequently but a temporary effect, if any at all. The effect lasts only as long as the treatment continues, the object of the treatment being to drive the fecal masses in the colon, which is almost exclusively the seat of constipation, in the direction of the least resistance, *i.e.* toward the rectum.

In order to obtain a more permanent result I have followed a way different from the ordinary one. I have, above all, endeavored to act upon the muscular fibers of the big intestine, the atonic condition

*If in a case of ulcus ventriculi we exercise with the percussion hammer a slight percussion on the epigastrium, we provoke a pain over a sharply-circumscribed area, which also remains for a little while. It is then quite immaterial where the ulcus is seated, on the arterior or posterior wall, as the percussion is transmitted in shape of oscillations through the contents of the stomach to the seat of the ulcus, and gives rise to the same kind of pain as if it were on its anterior wall.

On account of the novelty of the invention, there exists thus far only few reports about its having been tried, but these seem to speak in favor of it and confirm its utility and practical value.

†In 30 to 35 per cent. of cases the cancer does not give rise to any tumor.

‡Hyperchlorhydria makes an exception to this rule, since, as I have already mentioned, it requires more time before any improvement is noticeable, but the presence of chloric acid in a free state speaks in favor of the mentioned condition, as it is only in the few cases in which cancer develops on the basis of an ulcer that we find in this latter affection the chemical condition identical to that in hypochlorhydria or ulcus.

*In my practice in Paris as well as in this city I have frequently seen cases which had submitted to massage without the slightest results, and in which only the abdominal wall had been massaged, because the empirical masseur had disregarded these principles I have laid down. I remember among others one case in Paris, indeed, in which the abdominal wall was massaged for four months without the slightest benefit. Such occurrences are daily and not at all exceptional, and they will certainly bring massage into ill repute.

†Massage performed a short time after a meal is unpleasant to the patient as well as to the physician on account of the rippling noise produced.

of which is the real cause of constipation.* Massage, properly and rationally performed, restores, as in the corresponding condition of the stomach, the contractile power of the muscular fibers and a permanent cure may be obtained. In order to accomplish this, you proceed as follows: The patient is placed on his or on her right side; the small intestines fall over to the right side; the left one is then free, so that the sigmoid flexure may be properly massaged—as it is this one which is the most frequent and, at the same time, the most important seat of the affection in question. This is owing to its forming the lower part of the intestine, the fecal matters getting harder in their downward progress, and also to its having the shape of an S, this latter acting as a relative mechanical obstacle to the progress of the fæces. This is, although in much less degree, the case with the angle in which the transverse and descendent colon go over into each other (flexura lienalis), as this one is, according to Merkel,† more acute than the one on opposite side (flexura hepatica).

Besides, in this position the patient does not contract the rectus abdominis as much as in the one on the back, and it is then much easier to take hold of the large intestine and massage it. With the tip of the right thumb you go as deep as possible, trying with the end of the other fingers—just as in massage of the stomach—to seize as large a segment of colon as possible. As the transverse colon is very movable on account of its long mesenterium, it is well to proceed obliquely to its longitudinal axis. In this way a larger portion of the colon can be massaged at every stroke than by any other procedure.

In regard to the direction in which massage of the colon is to be practised, it appears to me to be immaterial if one starts or not at the cæcum and continues along the course of the large intestine toward the rectum, as one generally does, for my sole aim is, as I have said, to arrive at a permanent cure.

Toward the end of the séance, the whole intestinal pocket is massaged with both hands. The position of the patient in this last manœuvre is the same as when massaging the colon, because this position allows a better and firmer hold on the small intestines, falling, as it were, into one's hands.

Here, as in massage of the stomach, and for the same reason, it is only exceptionally that proper massage of the intestines can be performed at the very beginning. It usually requires a few days before this is accomplished; in some cases, indeed, in which the abdominal wall is particularly thick and resistant, a whole week and more may be spent in this preparatory massage.

The séance of massage is, as in that of the stomach affections, lasting about fifteen minutes.

The secret of success in massage of the bowels for constipation does not depend so much upon the various manipulations to be employed as upon a thorough knowledge of the anatomical, physiological, and pathological conditions of the organs to be treated. The manipulations to be employed are, like those in massage of the stomach, very simple, consisting only in frictions, and particularly pétrissage. In various treatises on massage you read descriptions of the different manipulations recommended not only in various diseases, but also in the same disease under different conditions.* I have always followed the school of Metzger, who has greatly simplified these manipulations and who uses but few of them.

I do not discuss the particular quality of the principal agent, the thumb, as I have already alluded to this. I repeat here that the lack of this qualification and other physical qualities is, in my opinion, one of the principal reasons for the failure of so many masseurs. This is especially the case with women, who very rarely have the proper strength in their fingers, especially in the thumb, and who exercise unnecessarily great force and thereby do a great deal of harm.

If you adopt a procedure, as I have just mentioned, you will almost never fail to obtain the most satisfactory results and not meet with disappointments, as is so often the case when you proceed empirically. Excellent results are often obtained even in some of the most inveterate and long-standing cases, in which all kinds of treatment, and especially all kinds of laxative remedies, have been employed without any relief. It is not at all uncommon or infrequent in daily practice to meet cases in which the symptoms have in this way become aggravated and in which the bowels become gradually accustomed to their use.† Purgatives will no longer act, unless the dose be increased. Moreover, the stomach becomes rebellious from the various irritating drugs and a gastritis medicamentosa is often the final result.

I must admit, however, that there are cases, and they are not so very infrequent, in which in spite of all properly performed massage, you don't get any favorable, or, at most, only a partial, result. These are cases in which the chief cause of constipation lies high up in the rectum in the neighborhood of the sphinct. tert. and is depending upon an atonic condition of the muscular fibers in that region. As these cases cannot be massaged through the abdominal wall, you have to go high up in the rectum with the tip of the right forefinger and thus massage the parts.

The results thus obtained have been most satisfactory; the contractile power has been restored to the intestine, and consequently also its activity. It is, of course, of the greatest importance for this purpose to have a long forefinger; a woman's finger will seldom reach high enough. I regard this method of massage as a real innovation, and of the greatest practical importance. I have practised this mode of massage even with girls, who are often great sufferers from constipation, without this condition being always caused by systemic affections, such as chlorosis, and can state that I have obtained most gratifying and unexpected permanent results. I have employed this last method also in women of good social standing without any objection on their part. Massage was here performed under the garments with all proper regard for the modesty of the patients.‡

Besides, there is sometimes, particularly in cases of very long standing of chronic constipation, relaxation and atony of the muscles surrounding the ampulla (expelling muscles). In such cases you will

*We do not believe that flabby and weak abdominal walls, which we see too often in women after many childbirths, exercise any noticeable influence upon the element constipation. I, at least, doubt the part the above condition is by many reputed to play in the production of constipation; at all events, it seems to me to be greatly exaggerated.

†Merkel, *Topographische Anatomie*, page 592.

*Yes, entire works have been written on this subject—as, for instance, those of Hoffa and Zabludowski.

†It is a common experience that enemata will act in the same way.

‡At times mothers, and of the best society, who have heard of its marvelous results, have urged me to adopt this procedure from the start in their daughters. I yield to their wishes, although I don't employ this method, of course, at the beginning of the treatment, from easily conceivable reasons. I only employ it when the other manipulations have not yielded the desired results. It is understood that, before rectal massage is resorted to, an enema must be given to the patient.

find this latter greatly dilated, so as to form a very large cavity containing extremely hard fecal balls.* These weakened muscles have to be massaged too, and most energetically.

SOME ILLUSTRATIVE CASES.

CASE VI.—Mrs. W., fifty years of age, was recommended to me, in the fall of 1899, by Dr. Keyes. Complained of sluggishness of the bowels for several years, but was always able to relieve it by enemata or slight laxatives. For the last three years the constipation became more obstinate, so that she was obliged to take purgatives up to three times daily. She had been massaged at different times by Swedish masseuses with but slight relief, and this of short duration. Other means yielded no better results. I massaged her for six weeks; result only partial. I then resorted to massage per rectum, with the result that after four weeks' treatment permanent recovery followed. Last spring I treated her husband, and I was then told that her bowels moved almost every day and that she was not obliged to resort to medicines any more.

CASE VII.—Mrs. C., twenty-five years of age, from Brooklyn. Has suffered from constipation almost all her life. Has used enemata in addition to cathartics. Her general condition has suffered from this. She looks pale; her complexion is of a sallow gray color. I treated her in the fall of 1902 for more than two months. In the last séances I employed rectal massage. Her improvement after this was wonderful. Bowels moved naturally every day. Was in family way this summer, but was not obliged to take medicine to move her bowels, while formerly she had to take purgatives almost every day. Her general condition is at present very good; she looks and feels splendid.

CASE VIII.—Miss C. M. of Brooklyn, fourteen years old, and a cousin of the former, was treated last February. Her bowels had always been more or less sluggish, but still always yielded to mild cathartics. Her mother urged me to apply rectal massage from the very start, but I refused to comply with her wishes. But when, after three weeks' treatment, I found the results not as satisfactory as I had wished, I yielded and applied it. After a fortnight she was perfectly well, and has remained so up to the present time.

The prolonged presence of fecal matters in the big intestine often causes real decomposition of its contents, formation of flatus and toxins of various nature, as ptomains, etc. These noxious matters may be absorbed and provoke a real general intoxication, being manifested under different forms. Several cases of this kind were treated by me, and I will relate two of them, which will prove it in a most evident way.

CASE IX.—B., a six-year-old girl from Boston. According to the history given by her parents, she has been suffering from constipation since she was born. Up to three months of age she had regular stools by giving her enemata. Since that time this procedure was no longer sufficient. They were obliged to administer to her a great many laxatives and purgatives of the American pharmacopœa. Last year, after having had only one stool during three days, she was seized by convulsions, which lasted twenty-four hours, and which the physicians attributed to a fecal accumulation in the colon. These convulsions ceased after emptying the bowels by an energetic purgative. The same attacks occurred several times, although less violent, and they ceased by resorting to the same means.

I saw the child in Paris in November, 1888. After having related to me all these details, the mother added that her little daughter, generally reserved and almost sullen, isolated herself as much as possible, and never took part in other children's plays. She was not, as she expressed it, like other children.

I tried massage, but without promising anything like a brilliant result. A fortnight later regular normal stools, without the enemata or purgatives. The treatment was continued for a month, after which the child was able to go to the toilet regularly at almost physiological intervals, without being obliged to have recourse to artificial means. No more convulsive seizures.

The child's character has quite changed. As the function of the intestine improved she became bright, lively, and no longer like her former self. Two slight relapses, a few months later, were easily overcome by some few days' massage, and her cure has remained permanent up to date.

CASE X.—Miss R., singer, twenty-eight years old, native of Hungary, complains of constipation almost since her childhood. For the last two years especially obstinate and annoying. Without purgatives she only goes to the toilet every three days. Little by little she lost her appetite; has become thin. Her complexion has changed and become cadaverous-like. The tone of her voice has also, little by little, become altered. All these changes she attributes to her constipation. She has become downhearted and melancholic. A physician from Vienna ordered a course of treatment at Marienbad; the result of it was quite unsatisfactory.

She came to see me in Paris in 1888, greatly emaciated. The walls of her abdomen extremely supple; her case particularly well adapted for massage.

Evident improvement after three weeks of massage. This one was resumed after a fortnight's stopping and continued for two months and a half, only interrupted during the menstrual period.

Formerly the fecal matters were very hard and had the shape of balls; the stools were attended with violent pains, so that she dreaded to go to stool. Now, after cessation of massage, painless movement almost every day. The fecal matters are well formed and of normal consistency. Her appetite satisfactory. I saw her again in July, 1890. The former beautiful complexion, as well as the tone of her voice, have returned. She has gained flesh and this great improvement of health seems to have completely banished all gloomy ideas.

Intestinal paresis is not at all rare in old people It is often mistaken for internal obstruction, or even for a real tumor. In my treatise of massage (Traite Théorique et Pratique du Massage," Paris 672 pages) I have referred to a case which was treated many years ago, and in which fecal vomiting had set in. Purgatives and enemata yielded no results. Toward the end of the second day, after five séances of massage, in which extremely hard fecal matters of a very repulsive odor were broken up, the patient recovered.

All that precedes applies to constipation depending upon an *atonic* condition of the intestine while the so-called *spastic* form has been entirely discarded, as it always has been regarded as not being susceptible to massage. I saw, then, with pleasure that Prof. V. Noorden, in his treatise o

*This coprostate can sometimes give rise to proctitis and even periproctitis, and this one in its turn, in women, to inflammation of ligamenta sacroiliaca with rectal stenosis; a fact to which Dr. A. Mueller in Munich of late has drawn attention as well to the curability of this last affection through massage alone, or with hot water injections (*Archiv fur Verdauungskrankheiten*, Bd. ix, H. 2).

colica mucosa (colitis membranacea)* speaks not only of massage as being absolutely inoffensive here, but even of the quite satisfactory results it yielded in his hands against the always existing causative factor, the constipation, always of spastic origin in this affection—provided the food given to the patient be one rich in residue.

I also had occasion to treat, in this country as well as in Paris, several cases of *diarrhœa* of long standing by massage, and employed the same manipulations as in the treatment of constipation, although with less force. The results have been, without exaggeration, most encouraging. In some of the cases the diarrhœa was complicated by chronic stomach trouble. It is quite evident that massage produces great changes in the tissues, in the glands, as well as in the motor element, modifying their anatomical structures, and consequently their physiological function. It is this interpretation which allows me to explain the effects of massage in constipation and in diarrhœa. Although the two conditions present an entirely different aspect, both are susceptible of being modified by our treatment through changes in the nutrition of the different histological elements in the intestine. In both affections the bowels are restored to their normal condition.

A word from one of my patients, who has been suffering for several years from stomach trouble and diarrhœa, furnishes a striking example of the results obtained. He frequently tells his friends "my physician has put a new stomach and new bowels into my body." This expression explains, in my opinion, most clearly the effect of abdominal massage.

PRACTICAL POINTS ON HERNIA.*

By F. D. GRAY, M.D.,
JERSEY CITY.
SURGEON TO CHRIST HOSPITAL AND NORTH HUDSON HOSPITAL.

HERNIA, in its broadest sense, is the escape from one of the closed cavities of the body of some part of its contents. Thus we may speak of a hernia cerebri, a hernia thoracis, or a hernia spinalis. Unless, however, otherwise designated, the term *hernia* is always understood to mean hernia *abdominalis*, which is characterized by the escape from the abdominal cavity of some part of its contents, at a point of lessened resistance in the wall, usually inherent, but occasionally acquired. In the nature of things, hernia abdominalis includes always three and sometimes four anatomical elements, viz., ring, canal, sac, and contents; the only inconstant features being the canal and the number of rings, according to the special form of hernia.

Along with these we usually associate in our minds the various superficial coverings, which, of course, are no constituent part of the rupture. There are two predisposing factors in hernia: first, the mobility and elasticity of most or all abdominal organs; second, the existence of various parietal points or areas of lessened resistance. The exciting cause is increased intraabdominal pressure, produced by excessive action of the muscular walls or diaphragm, or both, occasionally by a fall, striking on the feet or buttocks.

The fact that the inguinal and femoral rings, with the umbilicus, are the most vulnerable of the weak points, already mentioned, accounts for the preponderance of ruptures named after these localities, their frequency corresponding to the order given. Thus it is easy to overlook the possibility of hernia in other localities, such as the obturator foramen, sacrosciatic notch, vagina, rectum, and more especially the entire properitoneal space and various retroperitoneal recesses or depressions. Mr. Moynahan of Leeds published last winter an elaborate essay on retroperitoneal hernia, which has attracted widespread attention, and which emphasizes the more frequent occurrence of this variety than has hitherto been supposed. Even with the aid of explorative incision a small or moderate escape of intestine posterior to the peritoneum is easily overlooked unless this possibility is kept distinctly in mind and methodical search is made with a definite knowledge of the possible sites of such an accident. Six so-called recesses or fossæ exist which invite retroperitoneal herniæ, viz., the foramen of Winslow, the junction of duodenum and jejunum, the retrocæcal, inferior and superior, the ileocæcal, and the intersigmoid fossæ. Excepting the foramen of Winslow, they are all rather insignificant depressions in the peritoneum at the base or root of the mesentery, often too small to attract attention, except on careful inspection, but occasionally showing quite a spur with a corresponding pouch, and it is these rare conditions that favor this special form of hernia.

Of all the localities mentioned, the duodenojejunal recess is by far the most frequent site, and the anatomical relations are such that the upper circumference of the ring is always bounded by the origin of the superior mesenteric artery. Sometimes this particular type attains large dimensions. In the Anatomical Museum at Vienna are several remarkable specimens, the size of the sac showing that they must have contained not less than one-third of the intestinal tract.

It is important to bear in mind that while the usual contents of a hernial sac are intestine or omentum, or both, the inguinal, femoral, or vaginal may contain either a testicle or ovary, according to the sex, a portion of the urinary bladder, or even the gall-bladder, while the vermiform appendix is not a very infrequent occupant of right inguinal, or entirely unknown to the left inguinal hernia.

In size, ruptures vary from those containing only an epiploic appendage, or Littre's diverticulum, to one holding nearly or quite one-quarter of the intestinal tract and omentum.

A patient who recently applied to me for radical operation, is, I think worthy of mention in this respect. The patient weighed 240 pounds, and the inguinal rupture was readily visible, through his clothing, from across the street. I had sufficient curiosity to take his measurements, which were: circumference of the base, 30 inches; vertically over the middle, 14; and longitudinally, parallel with Poupart's ligament, 16. Coley, in a recent article, speaks of a hernia on which he operated as being "very large"—"the size of the fist." The one I have described was, in size and shape, more like the longitudinal half of a fair size watermelon. It is needless to say that although my patient had come 200 miles in hope of a radical cure, I resisted the temptation to operate.

The *diagnosis* of rupture is generally easy. A distinct tumor, having an impulse on coughing and a tympanitic note on percussion in either the inguinal, femoral or umbilical region, can hardly be overlooked or mistaken for anything else; but the existence of an obturator, sciatic, vaginal, or even a small femoral hernia, may easily escape notice, while the retroperitoneal type is generally discovered only at autopsy.

It is not sufficient to observe that hydrocele,

*Read at a meeting of the Hudson County, N. J., Medical Society.

varicocele, and enlarged inguinal or femoral glands must be differentiated from hernia by remembering that none of them give an impulse on coughing, and that hydrocele is usually translucent and does not extend through the inguinal canal, but we must also bear in mind that some incarcerated and most strangulated herniæ are not accompanied by impulse; while, on the other hand, some strangulated forms, especially when the constriction is in the sac, instead of at the ring, do give an impulse.

Remember also that a biloculor hydrocele of the cord, lying partly in the canal and partly within the abdominal cavity, may be to some extent reduced, and gives a distinct impulse on coughing or straining.

Perhaps the most important point in diagnosis, is that some patients have a small hernia, existing for months or years, of the presence of which they have been entirely ignorant, and yet which may be responsible for a series of symptoms—gastroenteric, or, perhaps, nervous, or that may suddenly cause the most acute picture of intestinal obstruction.

A surgeon of St. Paul told me recently that he was once called to a remote country place to operate on a young woman who had suffered for a long time with pains at varying intervals in the right iliac region. She had been treated for ovaritis and for hysteria, but her physician had finally concluded that the real trouble was chronic appendicitis. The situation of her pains led the surgeon to agree with the diagnosis, and he proceeded to remove an appendix which required some stretch of imagination to accept as the real cause of the trouble. The same strain of symptoms continued as before, until finally the girl's parents brought her to the city and presented themselves, with her, before the operator, declaring that, in their opinion, he had not in reality removed her appendix. In the course of conversation it developed that the attacks had always occurred while straining at stool, and, acting on this suggestion, the doctor had the patient disrobe and directed her to strain forcibly, when he at once discovered the presence of a small femoral hernia, whose existence had never been suspected. Operation on the rupture cured all the symptoms which had persisted in spite of the appendicectomy.

The narrator was reminded of this experience by our witnessing together an operation by one of the most distinguished abdominal surgeons in England, who removed an apparently healthy appendix on account of vague distress in that region, and being suspicious that he had not discovered the true pathology of the case, he began a thorough search of the neighborhood, which resulted in finding what was quite apparent from inside the abdomen, though not from without, the empty sac of a small femoral hernia that had never been suspected by either patient or surgeon, but which had, undoubtedly, at intervals, when it was down, produced all her symptoms.

It might seem superfluous to refer to the *management* of strangulated hernia. One could almost assume that, at the present time, nothing would be thought of in such a case but operation, provided the patient were not already too deeply collapsed to forbid any such procedure; yet not long ago I was called to see a man suffering from strangulated hernia for more than twenty-four hours, during which time repeated attempts at taxis had been made, and the patient was then in such profound collapse that I dared not operate, and he died within three hours. This experience proves that we should not yet cease to sound the warning *never to trifle with a strangulated hernia.*

Taxis should never be attempted in case of a hernia when we even suspect strangulation. The old rule "when in doubt, operate" applies nowhere more forcibly than here, and the standard we set for ourselves in appendicitis—the earlier the operation the simpler and the safer—is just as true of hernia with strangulation. I fear we still sometimes underestimate the rapidity with which a pinched intestine loses vitality, not only through injury by taxis, but even by a few hours delay. Strohmeyer said to his pupils: "If you find strangulation during the day it should be relieved before sundown; if during the night, it should be relieved before sunrise."

I would say: *Whenever* you find strangulation, in an *operable* patient, *do not waste an hour before relieving the condition by operation.*

One would think that the necessity for discussing the propriety of opening the sac before reducing the contents of any strangulated hernia had passed with that of taxis. That the question still remains open however, seems proved by the following extract, under the head of "Strangulated Hernia," from one of the latest and best treatises on surgery. It reads as follows: "The more voluminous the hernia the more important it is to avoid opening the sac; but in the majority of inguinal herniæ the surgeon must be prepared to open the sac." In other words, the author intimates that there are some strangulated herniæ in which opening of the sac may safely be omitted.

The fact that without such incision we must remain ignorant of the most important matter in the whole case, viz., the condition of the hernial contents, ought to decide this point without further remark.

It is obvious that no one should attempt an operation on strangulated hernia unless he is qualified and equipped as thoroughly as possible to deal with the various problems of intestinal resection and repair. Relieving constriction and reduction of hernial contents are well within the ability of many surgeons whose experience and technical requirements have not made them either competent judges of the necessity of a resection or given them the necessary dexterity and certainty in its performance.

Notwithstanding the fact that all herniotomies in cases of strangulation are done primarily to save life, yet, with the exception of the few cases in which the condition will permit of only the briefest operative procedure, the operation should be so planned as to prevent a recurrence of the condition. This brings us to the consideration of radical cure. So well established and of such frequency is this proceduce that we rarely think of it as comparatively new; but the professional memory of quite a number of my hearers must antedate the origin of what we to-day understand as the radical cure of hernia. During the past fifteen years, at least that many more or less famous surgeons have devised some special method for this purpose.

The majority of these deal with *inguinal* hernia, partly because of its greater frequency and partly because the male sex—which furnishes the most inguinal ruptures—feels the necessity of a radical cure more than does the female, in whom femoral and umbilical herniæ predominate, and whose mode of life and occupation better conform to truss treatment.

While most attention has been given to radical methods for inguinal hernia, some ingenious and practical methods have recently been devised for the cure of the femoral, umbilical, and ventral varieties. This is not an occasion for dealing exhaustively with details of technique. They would

fill a volume, but I will take the opportunity to emphasize a few simple and fundamental principles on which radical cure is based.

With the twofold object of returning such hernial contents as are in fit condition to their normal habitat within the abdomen, and the formation of such a barrier as will effectually prevent their again escaping, the indications are very definite. Accomplishment of the first purpose does not differ from the herniotomies of twenty-five to fifty years ago.

It is with the second and more difficult problem that we are chiefly concerned, viz., the building of the barrier. The materials for construction are the sac or peritoneum, the ring or rings and the canal, when one exists. The rings and canal furnish us with fibrous or aponeurotic and muscular structures, the question is how to use them. For a moment let us apply ourselves to the problem of reconstructing, as nearly as possible, a normal condition of things in the inguinal region where it has been deranged by a hernia formation.

First the peritoneal barrier must be replaced, and it is done in the most simple and effective manner by high ligature—or sometimes suture—of the neck of the sac at the point where it expands into the parietal peritoneum. Experience has proved that the complicated treatment of sac, making it serve as a buttress or pad, as in McEwan's operation, is not only unnecessary but futile, on account of the subsequent absorption of the infolded sac.

Next the internal ring should be reinforced by a suture which strengthens the external muscle oblique at that point.

Furthermore the canal and external ring are narrowed by suture of the conjoined tendon to Poupart's ligament, either over the undisturbed cord, by preference, or beneath the displaced cord, *à la* Bassini. Experience has shown that displacement of the cord, as practised by either Bassini or Halstead, is not essential to perfect results. The working out of those simple indications constitutes the whole problem of radical cure, and the less we complicate it the better our success.

A certain class of completely reducible herniæ, in which the sac can be easily separated up to the internal ring, without opening the canal, are best treated *à la* Kocher, by invaginating the sac and pushing it up through the muscles and aponeurosis above the ring, where it is twisted, sutured in place, and amputated. The canal and external ring are then narrowed by introduction of a few mattress sutures, passing from the aponeurosis of external oblique above, to Poupart's ligament below, while a finger is introduced into the canal to guard the cord from injury. This technique of Kocher's is not applicable to herniæ with adherent contents or whose sac is not readily separable from the cord—in other words, to irreducible or incarcerated forms.

Another variety of inguinal rupture is best managed by the aponeurotic overlapping, priority for which is claimed both by Girard of Bern and Andrews of Chicago. This is a method, the essential principles of which have been quite recently applied to umbilical and ventral types by the Mayos of Rochester, Minn. This technique is especially adapted to large ruptures with considerable stretching and thinning of the external oblique aponeurosis.

It involves division of the anterior wall of the canal and, after dissection and high ligature of the sac, attaching the lower edge of what I may term the upper leaf of the aponeurosis to Poupart's ligament by interrupted sutures, and over this bringing the lower leaf whose upper, or free edge is attached to the aponeurosis by continuous suture—thus materially narrowing the canal and furnishing an anterior wall consisting of a double layer of aponeurotic tissue.

The importance of narrowing the external ring as well as the canal must always be borne in mind, together with the danger of narrowing either ring or canal so much as to unduly constrict the cord.

The risks also of excessive manipulation of the cord or injury to its constituents parts should not be forgotten—especially when operating on children in whom the vas is so small and delicate as to increase the difficulty of recognizing and the danger of injuring it.

For the radical cure of direct inguinal hernia we must rely on suturing either the rectus aponeurosis alone, or combined with some of the muscle fibers, to the inner end of Poupart's ligament or to the periosteum of that portion of the public ramus.

All these methods of dealing with inguinal herniæ at the present day and in this country include the use of buried absorbable sutures and aim at primary wound union. McBurney's contention, in the late eighties, that healing by granulation with production of a dense cicatrix was desirable, has not proven popular. having unquestionably been based on a mistaken principle.

In Vienna they are still—or were a year ago—wedded to silk as a material for all buried sutures, as well as ligatures, and claimed practically no unpleasant results.

As I have already intimated, much less attention has been given to the radical cure of *femoral* hernia than to that of inguinal, partly for reasons already stated and, perhaps, also because the anatomy of the crural canal and its surroundings lends itself less readily to effective barrier formation, though of late this has been rather ingeniously overcome by at least two operators whom I have had the privilege of seeing during the past year. In brief. the methods for preventing recurrence of femoral hernia up to about two years ago were those of Bassini and the so-called "purse-string" operations of Cushing and Marcey, all of which, after high ligature of the sac, depend on some plan of suturing the pubic portion of the fascia lata to Poupart's ligament on one hand and to the falciform edge of the fascia lata on the other. While good results are claimed for the Bassini and the purse-string methods, it must be evident that neither plan aims to close what might properly be termed the internal ring of the femoral canal, viz., the crural arch, but merely shuts the external ring and outer portion of the canal.

Theoretically at least, the operations recently devised by Foederl, former chief assistant of the late Professor Gussenbauer of Vienna, and by Roux of Lausanne, Switzerland, are nearer the ideal, as they obtain firm closure of the crural arch on the median side of the femoral vessels, and so long as this holds no hernia can recur.

Foederl makes either a Bassini incision or supplements it with a vertical branch over the hernial sac. In the former case he incises the floor of the inguinal canal (or the fascia transversalis abdominis), thus reaching the preperitoneal space and the neck of the hernia, when the sac can be withdrawn from underneath Poupart's, nicking, if necessary, Gimbernat's ligament. Sometimes he reaches, separates, and ligates the sac from below Poupart's, as in the older methods. In either case he effects closure of the crural arch by suturing the conjoined tendon to Cooper's ligament or even to the periosteum on the horizontal Ramus, which you will observe also narrows or closes the external inguinal ring, thus forming a barrier against both inguinal and femoral herniæ.

Roux arrives at practically the same result by disposing of the sac after the usual method and then setting a small steel staple astride of Poupart's ligament internal to the iliac vessels and driving it home into the horizontal ramus of the pubes—an extremely expeditious and apparently effective method.

Inasmuch as the femoral canal gives exit to no structure like the spermatic cord, complete closure of both it and the rings is desirable.

An interesting and vital question in connection with radical cure of inguinal and femoral hernia is that of mortality.

I can do no better than quote from Coley of New York, who, in an exhaustive article published in the *Annals of Surgery* for June of this year, gives the death rate in a little over one thousand cases as two—about one-fifth of one per cent. His two fatalities occurred in the first five hundred cases and prior to 1898. Out of his second five hundred operations, done since that date, he has had no deaths.

Coley also gives the following interesting statistics: "At the clinics of Albert and Hochenegg, in Vienna, in 804 operations on 473 patients, all done prior to 1898, there were only three deaths. At the Johns Hopkins Hospital there was but one death in 459 operations, while in Carle's Clinic at Rome, 1,400 operations on 1,285 patients resulted in but two fatalities. Prior to 1890 the death rate was not far from 6 per cent.—enough to make one hesitate to advise operation as a routine matter, but since then the mortality has so steadily reduced, that it is, as already shown, practically nil, and the risk is, in skilled hands, certainly less than the risks of strangulation, even with the hernia apparently controlled by a truss."

As to the permanent cures, Coley's statistics are also interesting. Out of his series of 1,075 operations he has been able subsequently to trace seventeen relapses—about 1.5 per cent.

An analysis of the two series of relapsed cases, at the Hospital for Ruptured and Crippled in New York, shows that in one series 85 per cent. of the relapses occurred within the first six months, and 65 per cent. in the first year. In the second series, 65 per cent. of relapses took place within six months, and 80 per cent. within a year, while 13¾ per cent. occurred from one to two years after operation; but only 6¾ per cent. after two years have elapsed—so proving that recurrence after one year, and especially after two, is extremely rare.

It is probable that were it possible to follow all cases of operation done by surgeons of average skill the recurrences would be found to amount to about 2 per cent.—a very satisfactory showing for the operative procedure.

There remains to be considered among herniæ calling for radical cure the umbilical and ventral varieties. I need not remind you of the unsatisfactory nature of these herniæ as treated by any of the operative methods in vogue until quite recently. I speak, of course, of that form occurring in adults—usually of large size and accompanied by extensive adhesions. The prolonged operations, generally in obese patients, with tedious dissection of sac, from contents, naturally give a comparatively large mortality rate—while the fibrous ring is very unsatisfactory material for barrier formation. Some permanent results were secured by splitting the edges of the ring and uniting the broader surfaces thus obtained. Rather better success followed excision of the ring and closing the individual layers of the abdominal wall with buried absorbable sutures. Many cases, however, refused to hold unless one resorted to buried sutures of silver wire, with their frequent disadvantages. Not until within a few years has a really satisfactory technique been evolved, and for this we must thank the Mayo Brothers of Rochester, Minn. They began in 1895 applying the principles of aponeurotic overlapping to the radical cure of these ruptures with remarkable success.

At the last meeting of the American Medical Association, William J. Mayo reported thirty-five cases operated on by this method, the first ten by a lateral and the remainder by the vertical overlapping. Of these none have died, and but one had recurrence, that but partial, in a lateral overlapping which has since shown a somewhat boat-shaped distention. Their method includes excision of the umbilicus (omphalectomy) with, in most cases, an elliptical piece of skin and fat from the abdominal wall, and excision of sac and ring entire with amputation of sac contents (omentum) without attempt at liberation from the sac, unless intestine is adherent. All this is time-saving, and leaves the aponeurotic and muscular structures about the ring freely exposed for overlapping.

Depending on whether the abdominal laxity, present in most of these cases, is greater from side to side or from above downward, they then either open the median edges of the recti sheaths and lap them past each other like a double-breasted coat, fixating by sutures, or else they draw the same structures over each other vertically and secure them in a similar manner, aiming to produce 1½ to 2 inches overlap. Time forbids a detailed description of the technique.

The Doctors Mayo find that most of their operations are on women with pendulous abdomens—that is, with walls vertically elongated, and so most commonly now use the longitudinal overlapping. In the only case in which I have had an opportunity to apply this method (that of an old man with a combined umbilical and ventral hernia, the rings separated by an isthmus of about one-half inch), I found, on excision of sac and rings with amputation of a quantity of omentum, that I had to close a gap of nearly three inches each way. Lateral approximation was impossible, but I managed, even though the patient's abdomen was not pendulous, to secure about one-half inch vertical overlapping and sutured the recti in that position. This case was not ideal for the Mayo operation—but I doubt if I could have closed the defect by any other method and my patient made a good recovery, having now, at the end of two months, firm union of his recti.

If I may be permitted, in conclusion, a brief résumé of the practical points which I would especially emphasize, I would say:

Never forget the possibility of an unsuspected incipient or small hernia, as a possible cause of obscure abdominal symptoms or of obstruction.

Always remember the unusual as well as the ordinary locations of hernia.

Never practice taxis or delay operation in strangulated cases, nor neglect to open the sac and carefully inspect the contents.

Bear in mind the simple problem of radical cure—restoration of smooth flat peritoneum at the ring—and narrowing or closure of rings and canal—with peritoneum, aponeurosis, and muscle as building materials.

Transplantation of the cord is not an essential of the Bassini or of the Halstead method.

A successful operation on inguinal or femoral hernia dispenses with the necessity for even a temporary truss, but after cure of umbilical or

ventral herniæ a well-fitting abdominal supporter is a comfort.

Removal of the entire sac is not always necessary, and in the inguinal variety the distal portion is better left than to risk injury of the cord by a difficult and tedious dissection.

The radical operation is one of the safest and most certain in surgery; and on that account may properly be advised as routine measure.

On the other hand it should be remembered that in childhood all forms of hernia are usually curable by persistence in the use of a suitable truss, while after fifty-five the mortality rate increases, and as activity usually then decreases, a truss answers very well.

Finally young and middle aged adults—especially males pursuing an active life—ought by all means to have the benefit of an operation which carries practically no danger, relieves them from the discomforts and dangers incident to wearing a truss, and the inevitable, even if small risk, of strangulated hernia.

ORBITAL CELLULITIS; EMPYEMA OF THE ETHMOID CELLS AND THE FRONTAL SINUS; ABSCESS OF THE FRONTAL LOBE; PNEUMOCOCCÆMIA; DEATH.*

By E. GRUENING, M.D.,
NEW YORK.

The patient whose case is here related suffered from chronic suppuration of the ethmoid cells and the frontal sinus. He became infected by a pneumococcus invasion, the portal of infection being the nose. From here the infection traveled to the ethmoid cavities, the orbit, and the brain, passing by the frontal sinus. This fact was demonstrated clinically by the absence of tenderness in the region of the frontal sinus and, bacteriologically, by the sterility of the purulent contents. The pus taken from the nose, the ethmoid, the orbit, and the brain contained the pneumococcus. If in the descriptive title of this paper "orbital cellulitis" occupies the first place in the complex symptomatology of the case, it may be explained by the circumstance that it was the orbital affection with its inherent protrusion of the eyeball which caused the patient to be admitted to the eye wards of the hospital and brought under my care.

L. S., twenty-six years of age, a butcher, was admitted to the Mount Sinai Hospital on March 29, 1903. His left eye was chemotic and both lids were swollen. The motility of the eye upward was impaired and the globe was forced downward and forward. The pupil of the left eye was slightly larger than that of the right. Ophthalmoscopic examination negative. Marked tenderness over ethmoid bone, no tenderness over frontal sinus. Between the left middle turbinated body and the outer wall of the nose a layer of white pus. Temperature 103.8°, pulse 76, respiration 26.

Lungs, heart, spleen, ears normal. The patient was in a stuporous condition and could not be questioned as to the history of his disease. His relatives stated that six days ago he awoke in the early hours of the morning with much headache and pain in the left eye. The first three days he had chills and fever and a copious discharge from his nose. The pain in the left eye persisted, and after some time the patient became delirious, and finally stuporous.

On the day of admission, March 29, the patient was anæsthetized and operated upon. An incision down to the bone was made along the upper and inner orbital margins. The periosteum of the os planum and of the roof of the orbit was softened and perforated at several points. The entire os planum was carious, and the cavities of the ethmoid were full of pus and granulation tissue and communicated with the orbit, which also contained much pus. The lacrymal gland was displaced and lay in a pool of pus. The outer layer of the orbital process of the frontal bone forming the roof of the orbit was softened and discolored. It was, therefore, removed and the frontal sinus was entered from the orbit. The cavity of the sinus contained thickened mucous membrane, a quantity of pus, many mucous polypi, and an exostosis springing from the inner table of the orbital process. The sinus was then cleared of its pathological contents. The remaining bony walls appeared sound, and no communication could be found either with the sinus of the other side or the cranial cavity. Here the operation ended, and the large resulting cavity was loosely packed with iodoform gauze. A rubber draining tube was carried through the nose and a moist dressing applied.

The following day, March 30, the patient appeared but little improved. His mind was not clear, stupor and delirium alternated. The pulse ranged from 64 to 92, the temperature from 101.8° to 103.6o. At the first dressing all packings were removed and renewed moist.

March 31. Patient delirious the greater part of the day. At times he was quiet and answered questions rationally. In the course of the day the temperature rose to 105.4° with pulse 90 and respiration 28. He had a severe chill lasting twenty minutes. Leucocyte count 33,000. Lumbar puncture: 55 c.c. were obtained. Fluid clear. Spreads negative. Culture negative.

Late in the evening the patient had another chill. The temperature rose to 107.2°, pulse 124, respiration 28.

Sponge bath reduced the temperature to 105.8°. Packings removed. Profuse seropurulent discharge from wound. Packings renewed.

Cultures from pus of orbit, ethmoid, and nose: Pneumococcus. Culture from pus of frontal sinus: no growth.

April 1. Involuntary urination and defecation. Temperature 106.2°, pulse 96, respiration 34. Patient in deep coma. Ophthalmoscopic examination: Decided redness of left disk and considerable dilatation of retinal veins. In view of the negative character of the spinal fluid it was decided to explore the brain.

Osteotomy for exploration of the brain: No anæsthesia. The original incision along the inner margin of the orbit continued upward over the forehead, and the skin and periosteum of the flap were turned back. The inner plate of the orbital process was removed and the dura mater exposed. A stream of foul-smelling pus poured into the orbit. The dura matter was discolored and perforated on the under surface of the frontal lobe, and through the opening in the dura the pus continued to flow. After enlarging the opening in the dura, the finger was carried through it into a large pus cavity which had no limiting membrane. A dressing forceps was introduced into the abscess cavity and opened at various points. A number of pockets containing pus were emptied. The outer wound was flushed, but the abscess cavity was not irrigated. It was drained by means of narrow strips of moist selvaged gauze. Culture from brain abscess showed the presence of the pneumococcus.

Immediately after the operation the patient

*Read by title before the American Ophthalmological Society at the Congress at Washington.

answered questions rationally, but slowly, the temperature fell to 103.4°, and in the course of the night to 99.6°. Early in the morning of the following day the patient had a violent chill and lost consciousness. The temperature rose to 105.8°. Pulse 164, respiration 50, involuntary urination. Pulse very weak. Subcutaneous injection of hot normal salt solution. In the afternoon the patient had a general convulsion lasting two minutes, and later another lasting one minute.

April 3. Temperature 106°. Comatose. Involuntary urination. General convulsion lasting five minutes. The wound discharged purulent material and necrotic brain tissue.

April 4. Deep coma. Temperature 106.2°. Pulse 168. Chill lasting ten minutes. Subcutaneous infusion of salt solution. Respiration rapid, but lungs negative. Had five convulsions to-day. The wound continued to discharge foul-smelling pus and necrotic brain tissue. Wet dressings renewed. Report of blood culture taken April 2. Pneumococcus in plates and flasks.

April 5. Coma persists. Had thirteen convulsions to-day; total time, thirty-one minutes. White blood count 20,000. Unable to swallow. Fed by gavage. Temperature from 102.8° to 103°. Respiration rapid—50 to 60. At right base of lung large area of dulness. Bronchial voice and breathing. Mucous subcrepitant râles. At 10 o'clock pulmonary œdema. Cups applied. Œdema less marked. Foul discharge from wound.

April 6. Five convulsions since midnight. Pulse at times imperceptible. Died at 7.30 P.M. No autopsy.

36 East Fifty-seventh Street.

UNUSUAL SEQUELA OF A SUBMAMMARY HYPODERMOCLYSIS.

By O. PAUL HUMPSTONE, M.D.,
BROOKLYN, N. Y.
CLINICAL ASSISTANT TO THE SECOND MEDICAL AND OBSTETRICAL SERVICE, METHODIST EPISCOPAL HOSPITAL.

Mrs. S., a III-para, with a flat pelvis, came to term with a face presentation. After a prolonged first stage with no advance, attempt was made under chloroform to flex the head, during which attempt the cord prolapsed and would not remain replaced in uterus. A podalic version was easily accomplished, and the child then, giving evidences of the pressure on the cord, a breach extraction was quickly done, and a live child of 7 lb. 6 oz. delivered. Hemorrhage from a partially separated placenta led me to express the placenta at once. The uterus failed to contract promptly after being so quickly emptied, and profuse hemorrhage occurred, which was controlled only by packing the uterus and firmly holding the flabby fundus down. The patient was also profoundly shocked from the necessarily somewhat violent and prolonged procedures. An attempt to fill the blood-vessels and stimulate by heat seemed indicated.

Enteroclysis was tried and failed, because of the packing in the vagina. So with the needle of an aspirating syringe and a douche-bag rendered aseptic by boiling, 600 c.c. of decinormal salt solution at 116° F. (in the bag) was injected, half under the left breast and half under the right breast. Owing to the alarming condition of the patient this was done rapidly, but with constant rubbing and manipulation of the breasts to cause absorption. The fluid was promptly absorbed from beneath the left breast; but the right breast remained very much distended. This condition persisted in spite of massage and a tight breast binder. Palpation of the breast showed deep fluctuation, and the so-called "water boil" was recognized. On the second day, the patient having rallied, the breast became slightly tender and an ice-bag was applied beneath the tight binder. The temperature went up to 100.6°.

On the fourth day, the condition remaining the same, an attempt was made to aspirate the fluid, but without success, owing to the needle becoming clogged with fibrin and slough. An incision an inch long was made in the outer and lower part of the mass beneath the breast tissue, and about 200 c.c. of turbid fluid, containing masses of fibrin and slough, was evacuated, and a drainage tube was inserted into the cavity. Cultures of the fluid were negative. Microscopically it showed many leucocytes, fibrin, granular débris, and fat globules.

No milk had appeared in either breast which could be expressed from the nipples. The second day after draining the cavity about 225 c.c. of milk escaped from the sinus during the twenty-four hours. Examination showed the milk to come, not from cut milk ducts but from deep within the cavity. The tube was removed and the sinus continued to discharge from 200 c.c. to 300 c.c. of milk daily. No milk appeared at nipple on pressure, and the other breast did not functionate. Belladonna ointment of a 10-per-cent. strength was applied thickly over the breast and a tight binder kept on. Under this treatment the milk stopped suddenly in four weeks, and in a few days the sinus healed. In another week the breast resumed the size and constituency of the other.

The conclusions resulting from this experience, while possibly not new, should always be in one's mind:

1. Hypodermoclysis should, under all conditions, be given slowly and not too hot. Particularly is this true when, because of shock, the lymph sinuses are slow in absorbing the fluid.

2. If a "water boil" is formed it should be evacuated promptly to prevent the pressure from causing sloughing of the under surface of the breast, thus opening milk ducts which in a pregnant woman at least may secrete and delay prompt healing.

92 Greene Avenue.

A Medical View of the Prevention of Appendicitis.—A. G. Browne, Jr., finds a predisposing cause of appendicitis in the embryological structure of the organ, for by inherited uselessness it becomes a tissue of low resisting power. Moreover, its position and anatomical mechanism subject it to frequent attack. Browne believes that the causative factor of the disease is some gastrointestinal derangement, such as gastritis or duodenitis. Every patient therefore with gastric and intestinal complaints, acute or chronic, is a candidate for appendicitis and his cæcum should be kept under constant surveillance.—*Virginia Medical Semimonthly.*

Treatment of Pelvic Diseases in the Female Insane.—Ernest A. Hall reports a number of cases and writes that his experience justifies him in stating that pelvic disease in the insane is not infrequent, and that in a certain percentage of cases the removal of the physical disease is followed by the restoration of the mental faculties. He is convinced that pelvic disease in the insane should receive operative treatment, and that it is advisable that either special detention hospitals or special wards be provided in our general hospitals, where recent cases of insanity may receive appropriate treatment; also that the Lunacy Act be amended so as to allow the commitment of suitable cases for trial treatment in such detention hospitals to be subsequently removed to the State hospital, should such treatment prove insufficient. A competent gynecologist should be associated with all State hospitals for the insane.—*Canada Lancet.*

RECENT ADVANCES IN THE TREATMENT OF NEPHRITIS.

IN a recent issue of the London *Practitioner*, Dr. Thomas J. Horder remarks that there are few patients whose treatment taxes the physician's skill more than the nephritics. Considering that van Noorden's results mark a distinct advance in our knowledge, Harder starts by epitomizing them. The chief point in treatment is *the course of the disease as modified by different dietaries*. The degree of albuminuria is to be interpreted with caution. Only in acute nephritis perhaps is the amount a conclusive index of good or bad results. In subacute cases with œdema, fluctuations in the albumin may occur quite independently of the diet. In contracted kidney the amount of albumin is notoriously a fallacious guide. Any sudden change in the diet is apt to involve an increase in the albumin. A high figure for the latter is apt to denote an acute exacerbation of the process rather than the degree of permanent renal damage. The third criterion is *the excreting power of the diseased organ*, which may be tested in various ways, van Noorden preferring to test the eliminating power for the food principles themselves. As the result of many observations in acute nephritis van Noorden finds that urea, creatinin, pigments, hippuric acid, phosphates, and inorganic sulphates are excreted with difficulty, and that in the early stages water is eliminated with great difficulty. On the other hand, uric acid, xanthin bases, aromatics, ammonia, amido-acids, chlorides and carbonates are easily excreted. Wherefore we must avoid meat extracts and broths and eggs, with a view of minimizing the creatinin; hæmoglobin containing foods, on account of the resulting pigments; and green vegetables, on account of the hippuric acid formed. On account of the resulting urea and phosphates, milk is to be given sparingly, and water must also be restricted. In all but severe cases, one can give with impunity, cream, butter, white vegetable soups, puddings made from oatmeal, flour or maize, and white bread. With milk a little calcium carbonate is always to be given in order to secure the precipitation of the phosphates and their consequent elimination in the fæces. In severe cases with threatening suppression and increasing œdema, van Noorden gives a pint of milk a day without other fluid, thirst being relieved by a little ice or by very small quantities of water. Full diaphoresis is encouraged. After four or five days, or in less severe cases, two and a half pints of milk a day is allowable, with one-half to three-fourths of a pint of sweetened and sterilized cream; and if more food is necessary, some of the allowable articles are to be added. Where the excretion of water is good or where it is increasing after a period of deficiency, liquids should be given freely, as under these conditions they do good. Convalescence demands a dietary larger in amount and variety. Legumes, cream cheese, and a little egg or meat, may now be given, the total albuminoids being, however, kept within 100 grams a day. If œdema reappear, the skin must be stimulated or a dry climate chosen. Diuretics are never of value in any stage.

In contracted kidney the one problem is to spare the organ. Alcohol, condiments (such as pepper, ginger, mustard, and spices) except salt, vinegar, and lemons, are to be interdicted, as are also celery, radishes, and asparagus. Salicylic acid, resorcin, lead, boric acid, mercury, iodoform, and tar, should be avoided. Coffee, tea, and tobacco are injurious, as they dissipate instead of conserving cardiac energy. Except strong broths and extracts, and "high" game, meats are allowable. A varied and fairly liberal dietary is suitable, but most cases do best on a limited supply of water, and the total supply of fluids should not exceed two and a half pints a day. This limit agrees even with the gouty nephritics. Where, as does not usually occur, the restriction of fluids operates to hamper elimination, one "drinking" day a week should be allowed.

Recently, Widal, Lemierre, and Javal have found in several cases of parenchymatous nephritis a relation to exist between the amount of salt ingested and that excreted, and that of increase of weight and œdema; retention of the chlorides corresponding to increase in both the latter. They are thus led to propose a "cure by dechlorination," and in one case they found that on a diet containing only 1.5 grams of salt, continued for eighteen days, a total disappearance of the œdema took place with a reduction of the albumin from 5.32 to 0.75 grams.

Discussing "Curable Albuminuria," G. Lyon holds that these cases are constitutional and not local, an inheritance from parents with gout, gravel, diabetes, obesity, or megrim. And here treatment is to be directed toward the general health. Lately Lenossier and Lemaine have shown that, even in health, kidney function is interfered with by the erect posture. In view of the marked effect of the latter on the albuminuria, it is important that the patient rest in the recumbent posture for at least one hour after meals. Indeed, any prolonged assumption of the erect posture should be interdicted.

In the uræmia of acute (and of acute exacerbation of chronic) nephritis, the value of venesection is attested by several observers. Marked diaphoresis and diuresis with diminished albuminuria, ensue. Marsden considers venesection especially indicated where, following overstrain and dilatation of the left ventricle, the right heart becomes dilated. Diaphoresis alone seems useless unless it is quickly followed by diuresis; and it may, by further increasing the already high osmotic tension of the serum, do harm. For the same reason, only hypotonic saline solutions (0.5 per cent. solutions ad maximum) should be infused.

As regards surgical treatment, while several surgeons have published records of operation on genuine cases of Bright's disease, and there seems no doubt that in many cases improvement has followed the

operation, it is yet too soon to say whether it is permanent. Patel and Cavaillon, discussing the question somewhat fully, give the following as indications for operation in "nephritis": (1) nephropexy in the albuminuria of displaced kidney; (2) puncture or incision of the capsule in acute nephritis with great congestion; (3) capsulectomy in chronic nephritis; (4) nephrectomy where one kidney is quite useless and it is desired to prevent its reflex inhibition of its sound fellow. Operating on dogs, Johnson finds that two months after capsulectomy a new capsule of homogeneous fibrous tissue thicker than the original, has been formed. No considerable anastomosis between the intrarenal and perirenal vessels was found. Whatever relief follows capsulectomy would, therefore, seem to result from relief of tension and not from the establishment of a collateral circulation.

THE DRUG HABIT AND A SUGGESTED ANTI-NARCOTIC LAW.

THERE would seem to be forthcoming irrefutable evidence that the drug habit is prevalent in this country, and that it is on the increase. The use of cocaine is said, by those who are qualified to speak with authority, to have gained headway with great rapidity within recent years, especially among the ignorant negroes of the South. This evil, however, is by no means confined to the South, but exists to a greater or less extent in the Middle States, is beginning to invade the North, and, in fact, is known throughout the entire land. That steps should be taken as promptly as possible to prevent ignorant and irresponsible persons from obtaining harmful drugs at will, is too self-evident a proposition to need much emphasis. Although, narcotics are, in certain portions of the United States, sold by individuals who have no right so to do, yet, on the other hand, many druggists are guilty of the practice of wrongfully retailing such drugs. The leading druggists the country through, have come to a realization of the situation. They now are aware that druggists in many instances are responsible for the growth of the cocaine and narcotic habits, and also perceive that, if the indiscriminate sale of these poisons be not stopped, that a slur will be cast upon the whole profession of pharmacy. During last year anti-cocaine or anti-narcotic laws were passed in the States of Georgia, Illinois, Pennsylvania, and Texas, while several other States have declared their intentions of invoking the aid of legislation with the same end in view.

The American Pharmaceutical Association, some two years ago, concluded that the question was one that intimately concerned the good name of its members, as well as the health of the community at large, and appointed a committee to look into the matter thoroughly, and further requested Dr. James H. Beal of Scio, Ohio, to draw up a specimen measure. Professor Beal presented his draft at the last meeting of the association, held in September, and after this being discussed and amended it was approved. The most salient parts of the bill are as follows: Section 1. That it shall be unlawful for any person, firm, or corporation to sell, furnish, or give away any cocaine, salts of cocaine, or preparations containing any cocaine or salts of cocaine, or morphine or opium in any form, or chloral hydrate, except upon the original written order or prescription of a lawfully authorized practitioner of medicine, dentistry, or veterinary medicine, such prescription to be written in clear terms, or if ordered by a practitioner of veterinary medicine, shall state the kind of animal for which ordered, and shall be signed by the person giving the prescription or order. The order or prescription shall be permanently retained on file by the person, firm, or corporation who shall compound or dispense the articles ordered or prescribed, and it shall not be recompounded or dispensed a second time, except upon the written order of the original prescriber.

Provided, however, that the above provisions shall not apply to preparations containing not more than two grains of opium, or not more than one-eighth grain of morphine, or not more than two grains of chloral hydrate, or not more than one-sixteenth grain of cocaine, in one fluid ounce, or if solid preparation in one avoirdupois ounce.

Provided, also, that the above provisions shall not apply to preparations recommended in good faith for diarrhœa and cholera, each bottle or package of which is accompanied by specific directions for use, nor to liniments nor ointments when plainly labeled "for external use only." And provided, further, that the above provisions shall not apply to sales at wholesale by jobbers, wholesalers, and manufacturers to retail druggists, nor to sales at retail by retail druggists to regular practitioners of medicine, dentistry, or veterinary medicine, nor to sales made to manufacturers of proprietary or pharmaceutical preparations for use in the manufacture of such preparations, nor to sales to hospitals, colleges, scientific or public institutions. Section 2. It shall be unlawful for any practitioner of medicine, dentistry, or veterinary medicine to furnish to or to prescribe for the use of any habitual user of the same any cocaine or morphine, or any salt or compound of cocaine or morphine, or opium or chloral hydrate in whatsoever form. And it shall also be unlawful for any practitioner of dentistry to prescribe any of the foregoing substances for any person not under his treatment in the regular line of his profession, or for any practitioner of veterinary medicine to prescribe any of the foregoing substances for the use of any human being.

Provided, however, that the provisions of this section shall not be construed to prevent any lawfully authorized practitioner of medicine from prescribing in good faith for the use of any habitual user of narcotic drugs such substances as he may deem necessary for the treatment of such habit. Violations of the provisions of this act will be met with a sufficiently heavy fine.

This measure has already been introduced into Congress as a part of a general poison bill, and has been referred to the Committee on the District of Columbia.

Legislation enacted on the lines proposed by Professor Beal would do much to check the growing tendency to the drug habit. The time is ripe for a halt to be called, but so long as some druggists have no scruples in selling narcotics, but little can be effected to stop the evil. It is a healthy sign that the Pharmaceutical Association has seen fit to take the matter in hand.

HODGKIN'S DISEASE.

ALTHOUGH the etiology of the disorder first described by Hodgkin in 1832, and known by his name, remains undiscovered, its symptomatology and morbid anatomy have been thoroughly worked out. The most recent evidence would tend to show that the affection is not, as has been suggested by some, due to the activity of tubercle-bacilli, and, therefore, is not a form of lymphatic tuberculosis. The lesions considered characteristic consist in hyperplasia of lymphadenoid tissue, with proliferation of reticular endothelial cells, and the formation of mononuclear and multinuclear giant-cells. Marked thickening of the reticular network of the glands takes place, with the development of coarse anastomosing bands of connective tissue. Eosinophile leucocytes are present in the affected tissues in large numbers. Together with the myelocytes, their number is increased also in the bone-marrow. The results of an admirable study of the pathologic histology of Hodgkin's disease made by Dr. Warfield T. Longcope, resident pathologist in the Pennsylvania Hospital, have recently been published in the first number of the Bulletin of the Ayer Clinical Laboratory of the Pennsylvania Hospital. The tissues from six cases were examined carefully, and the conclusion was reached that the disease must be considered as a distinct clinical and pathologic entity. The morbid process originates in lymphoid tissue, and during the course of the disease new lymph-glands are constantly being formed, which ultimately become the seat of lymphomatous growths. In rare instances the retroperitoneal lymph-glands may be the only group affected.

PHYSICIANS' FEES AND THE SHARP PRACTICES OF PATIENTS.

The question of physician's fees is a vexed one, and is a source of much worry, inconvenience, and discouragement to medical practitioners throughout the civilized world. Doctors themselves are agreed that as regards the payment of their dues they are an ill-used body of men. The general public, however, judging from their actions, seem to take an entirely different view of the matter, and, as a rule, treat the bills of medical men with indifference, and put off the payment thereof to a convenient season or neglect to liquidate these debts. It is refreshing, therefore, to find that there are persons outside the medical profession who possess a conscience, and who are in sympathy with doctors in this particular trouble. Such a one has recently sent a communication to the MEDICAL RECORD, in which some of the more obvious means of cheating the physician resorted to by unscrupulous or inconsiderate patients are pointed out, and suggestions are made whereby the doctor may be enabled to avoid giving advice to those who are unwilling to pay for the same.

The writer first draws attention to the fact that the telephone is frequently brought into use to the detriment of the physician. An individual will telephone to a medical man describing symptoms, and generally receives advice as to treatment, for which the giver gets nothing, indeed there is no scale of charges for advice thus tendered. Our correspondent suggests that in order to stop this sharp practice, physicians should charge for "telephone advice," leaving the amount to their discretion, and stating on prescription blanks and bill heads that this procedure would be followed. Another inconvenience and injustice to which the long-suffering doctor is often subjected, is the habit indulged in by some people of waylaying their medical attendant in the street or at a neighbor's house and extracting from him advice. Of course this is done so as to evade the fee which would have to be forthcoming if such cunning individuals went to a physician's office. The writer thinks that "these ways that are dark, and tricks that are vain" should not be allowed to pass without at least a protest, while, if the doctor took matters into his own hands and had a full understanding with his patients that a charge would be made in those instances in which actual professional advice or a prescription was given, that to this decidedly underhand habit would be put an end once and for all. The writer explicitly vouches for the truth of the statements made, and declares that neighbors have confessed without shame that they have employed the above-mentioned devious methods to evade the payment of an office fee.

The physician's position is a peculiar one. A tradesman, as a butcher or greengrocer, simply delivers his goods at the door and expects his money whenever due. If payment is not promptly made, he, without scruple, takes steps to recover his debt. With him it is merely business, and sentiment does not enter into the case. The doctor, on the other hand, from the very nature of his calling, is more often than not a friend of the family; he is cognizant, to a greater or less extent, of the pecuniary situation of his patients, and not infrequently forbears to press the payment of an account for personal and sympathetic reasons. His forbearance is mistaken, and his tolerance abused, and as a consequence not only is he the last man to be paid, but he is cheated—as no other class of bread-earners is cheated—by that large army of persons who want to get something for nothing. The suggestions of our correspondent are worthy of consideration by medical men.

MOSQUITO EXTERMINATION AN ENGINEERING PROBLEM.

At the "General Convention to Consider the Questions Involved in Mosquito Extermination," held in the rooms of the Board of Trade and Transportation, New York, on December 16 last, Mr. Henry Clay Weeks read a paper, the gist of which was as follows: "Mosquito extermination is essentially an engineering problem. Other features of the work are highly important, but the engineer may best determine and carry out plans to get rid of the breeding-places, often involving the redemption of thousands of acres of marsh or saturated areas of vast value. Heretofore engineering has been for and not against the mosquito. Breeding-places have almost universally been caused by engineering works. This applies to highway, railroad, and landscape engineers. The result has been often the depopulation of valuable sections by malaria, and its bearers, the anopheles. The better term is "economic engineering," for the work covers a wide range, besides simple extermination—the utilization of large areas for agriculture and even for habitation and the improvement in living conditions of a vast population."

The foregoing quotation is a true presentation of the facts of the case. Engineering can undoubtedly do more than any profession toward the extermination of the mosquito. It is undoubtedly also correct that up to the present time engineers have greatly assisted in the propagation of mosquitos, and consequently in the spread of malarial fever. It is more than likely, although no definite information on the subject is forthcoming, that the engineering

works of the French in the cutting of the Isthmus of Panama have rendered the locality about the route more infested by mosquitos and more malarious than before, and numerous other instances of a like nature could doubtless be given. The question of mosquito extermination is essentially an engineering question. Drainage, filling, and, in some cases, the construction of dams or tide gates to control water levels may solve for all time the mosquito problem. The encouraging feature of the matter is that engineers themselves now have come to the conclusion that such is the case. All that is needed is money, and private and public coöperation to exterminate the mosquito and drive away malaria. Of course, this desirable result can be reached but slowly. In civilized countries the work can be proceeded with at once, but in far-away tropical countries mosquitos will continue until the land is opened up by the white man.

Reforms Needed in the Methods of Administering Anæsthetics.

Mr. Frederic Hewitt, an anæsthetist of great repute in London, contributes to *Lancet*, December 12, a letter urging the need of further reforms in the department of anæsthetics. He asserts that there is little or no uniformity in the existing arrangements for administering anæsthetics. At some hospitals the great majority of anæsthetics are administered by officially appointed anæsthetists, who are, as a rule, non-resident. At other institutions the great bulk of the anæsthetics are given by clinical assistants, house surgeons, or students, the surgeons holding themselves more or less responsible for the safety of their patients. According to the writer, the result of this unsatisfactory state of things is as follows: In the first place, the public as represented by the patients who are subjected to the unskilled anæsthetization incidental to the present systems, are unnecessarily inconvenienced and alarmed. In the second place, the success of operations is greatly interfered with. In the third place, human life is unnecessarily sacrificed. These are the conclusions reached: (1) In all institutions in which anæsthetics are frequently administered special departments should be formed. (2) In all such institutions there should be at least one special officer to control the department, and in large hospitals, such an additional staff of anæsthetists as would provide for the efficient working of the department. (3) Resident anæsthetists should be appointed in all hospitals in which the work of the department calls for such an office, and these posts should, as far as possible, be filled by previous house officers. (4) In hospital practice the administration of every anæsthetic should be either conducted or supervised by an officially appointed anæsthetist, and no anæsthetic should ever be given unless two qualified persons are present. (5) In appointing senior anæsthetists in the future, an endeavor should be made to obtain the services of those possessing the highest medical and surgical qualifications. At each hospital the officer at the head of the department should be a member of the staff. (6) In large hospitals and schools the duties of the head of the department should be upon the following lines: (*a*) he should personally supervise the department, report at least once annually to the lay and medical authorities as to its working, and keep records as to the anæsthetics administered; (*b*) he should personally inquire into any accident that may have occurred during anæsthesia, and comment upon the same in his annual report; (*c*) he should be responsible for the system of instruction to the students, giving lectures and demonstrations according to the requirements of the hospital and school; (*d*) he should provide, if possible, for a proper examination of patients before anæsthetics are administered, and in any exceptional case should confer with the medical or surgical officer under whose care the patient may be; and (*e*) he should take such a share in the practical work of the department as may be specified by the authorities electing officers for the department.

The fact has been for long notorious that anæsthetics are often administered by unskilful hands, and that thereby many avoidable deaths occur. There is every reason that anæsthetists should be qualified by experience to fulfil their duties properly, and the time has come when this question should be thoroughly considered, and necessary reforms introduced.

Diabetes and the Islands of Langerhans.

The *London Hospital*, December 26, reviews the progress made in investigations as to the causes of diabetes. Pflüger in his *Archives*, 1903, suggests that the change of glycogen into sugar is stimulated by impulses coming from various parts of the body as their need for sugar rises or falls, and on the other hand it is checked by the antidiastase found in the pancreas. On the balance of these forces the absence of diabetes depends. The local stimuli usually act through the splanchnic nerves, but in some cases by secretions poured into the blood. He holds to the belief that the transformation is affected by a ferment and seems to overlook the strong evidence which has been brought against the presence of such a ferment. The *Hospital* article touches on the latest views propounded by various authorities with regard to diabetes, including those of Rumpf, who is of the opinion that coma may be due to the loss of water and dehydration of the tissues, and then proceeds to discuss an article by A. E. Finney, which appeared in *The American Journal of the Medical Sciences*, in which he deals with the islands of Langerhans in connection with diabetes. These structures were first described in 1869, and consist of small spherical masses of epithelial cells, just visible to the naked eye, lying in irregular columns separated by tortuous vessels, and are most numerous in the tail and next in the body of the pancreas, where they are distributed among the acini, though they have no connection with excretory ducts. Laguesse, in 1893, first suggested that they furnish the secretion which regulates the metabolism of the carbohydrates. In the embryo they are formed even before the acini, and remain more numerous in childhood than in adult life. Now as long as a portion of the pancreas remains in the body pancreatic diabetes does not occur, and even ligature of the duct fails to produce it. The explanation seems to be that since after ligature the islands remain intact, though the rest of the gland wastes away, the islands supply the needful secretion. Though many cases of diabetes have been found in which the islands were normal, yet in a large proportion marked changes were present. The author's dissection of thirty-five cases lead him to the conclusion that morbid changes in the islands may take place independently of those in the rest of the pancreatic tissue, at least to a great extent, that diabetes may occur when the islands alone are affected by morbid changes; but, on the other hand the disease may be found when the islands are apparently healthy, and in this case the affection may be of nervous origin of the alimentary type. Slight lesions may be found where no diabetes exists, if a healthy sufficient number of islands remain to carry on the work. The writer in the *Hospital* concludes by stating that the discus-

sion of the functions of these islands of Langerhans has been joined in by numerous writers, especially during the past three years, while its importance has been increased by the discovery of adrenalian glycosuria. The observations of investigators upon the action of the adrenals and their influence upon the excretion of sugar in the urine are then quoted.

The islands of Langerhans exert some influence on the production of diabetes, but the extent of this influence is by no means clearly known. Further investigations may decide more definitely the importance of these structures in connection with diabetes.

Relating to Whiskey.

Both the drug habit and the drink habit loom large in the public eye at the present time. Efforts are constantly being put forth to check these practices. Spirit drinking may be said to be the bane of the so-called Anglo-Saxon race, for after all the drug habit is not nearly so widespread, either in this country or in Great Britain, as in certain parts of the European Continent. Of all the beverages with which the inhabitants of the United States and of Great Britain stupefy their brains and dull their intellects, whiskey appears to be the one most in favor. Its consumption, especially in England and Scotland, has increased enormously within recent years. In fact, so disastrous have been the results of the whiskey habit on the other side, that special inquiries have been instituted to investigate the matter exhaustively. The *British Medical Journal*, December 26, has a special article which gives the outcome of investigations into the modes of manufacturing whiskey in England and Scotland. These were the conclusions come to: It appears, first, when whiskey began to come into extensive use it was made from malted barley, and that such reputation as it possesses for relative wholesomeness was founded on the malt whiskey. Second, we now learn that this type has been replaced by two-thirds of the total consumption by a spirit made from different materials by a different process, and that the by-products it contains are, as might have been anticipated, different. Third, it appears that knowledge of the chemical nature of these by-products, though it has increased in recent years, is still very imperfect, and that practically nothing is known as to their physiological action; and, lastly, that nevertheless this new spirit is sold as whiskey both at home and in the colonies, and is used for blending with malt whiskey, the blend being in some instances so labelled as to give the purchaser the impression that it is malt whiskey.

The question as to whether the consumption of alcohol at all is conducive to good health has been answered in the negative by the majority of scientists who have investigated the matter; while all are of one mind in that excessive drinking of alcohol is injurious in a high degree. However, if a person drinks spirits, he should at any rate be able to obtain the kind of spirits he desires. When he asks for old whiskey it is not right that he should be given a product mysteriously prepared and chemically matured. This is an age of sham and delusion, so far as many foods and most spirituous beverages are concerned. There is needed a Dickens or a Read to expose the methods in vogue among manufacturers of preserved foods and of alcoholic beverages. Probably, if the subject were thoroughly probed, it would be found that American makers of whiskey are as conscienceless as are their British brothers and care little for the public health so long as they can fill their own pockets. Adulteration of any kind should be strictly prohibited, or if practised the public should have the means of knowing the methods employed. By far the safest and most satisfactory plan, however, would be to prohibit adulteration entirely.

Nervous Dyspepsia.

Dr. Andrew MacFarlane writes in the jubilee number of the *Albany Medical Annals* concerning this extremely and increasingly frequent condition. Dr. MacFarlane says truly, "Nervous dyspepsia is a functional disorder of the stomach which has become the most common of gastric diseases and with its protean form may imitate, oftentimes successfully, any organic disease." The diagnosis of nervous dyspepsia is in a high degree difficult, and as the writer points out, the question has been raised as to whether nervous dyspepsia is a disease *per se* or only one of the manifestations of neurasthenia. The affection is developed by mental worry and a consequent inattention to the rules of health, and especially so far as eating and drinking is concerned. The experiments of Pawlow and his associates have shown that it is neither the chemical nor mechanical stimulation of the buccal mucous membrane which is responsible for the gastric secretion, but the eager desire for food and the feeling of satisfaction and contentment derived from its enjoyment. Gastric secretion appears at the call of appetite; and when appetite is absent so also is the gastric juice.

Dr. MacFarlane demonstrates the manner in which nervous dyspepsia develops, and describes the distressing physical symptoms which are characteristic of this state. The mind, too, becomes involved, and the sufferer has various mental symptoms which augment *pari passu* with the increase of the bodily ills. The complaint exhibits a variable course; for days together a patient with nervous dyspepsia may feel in good health, and then suddenly, without apparent cause, he will revert to his former condition.

With regard to treatment, the writer says "that this should consist first in gaining the entire confidence of the patient by your manifest comprehension of his condition and by the assurance you are thus able to give him that he is not suffering from an organic disease of the stomach. The nervous system in general should be strengthened and improved, and the digestive function in particular. If the patient is well-nourished the treatment is largely that of neurasthenia. If he is emaciated, which is usually the case, the treatment should be directed to the improvement of the nutrition. For this purpose as full a diet as possible should be given with regulated out-of-door exercise and gymnastics. In many cases a modified Weir-Mitchell cure is most effective." Medicine is of little avail and should be given to meet the symptoms. Change, of scene, if possible, and a natural animal existence, free from care and worry, is the only panacea for nervous dyspepsia.

Dr. MacFarlane, of course, only writes of the symptoms, diagnosis, and treatment of nervous dyspepsia, and says nothing of its prevention. The condition is a concomitant of the present-day life in towns, the endless striving for wealth and the worries incidental to its pursuit. The ordinary city business man leads an obviously unhealthy life. As a rule he neither eats, sleeps, nor exercises properly. When he is in his office, in addition to being in an atmosphere not generally conducive to good health, his mind is taken up with stress of business, and he pays but scant attention to the needs of his stomach. In many instances such a man is apt to eat injudiciously and too quickly, while his errors with regard to what he drinks are even more patent.

The conservation of good health in the majority of cases lies with the individual. A city man has not the advantages of his country brother in the way of preserving "the sound mind in the sound body," but he could if he so resolved, use both his mind and body with more discretion than he usually does use them. The present trend of medicine is toward prevention rather than cure, and in no one disease does this precept apply more fittingly than to the distressing condition known as nervous dyspepsia.

News of the Week.

The International Congress for Tuberculosis.—Under the auspices of the Maryland Tuberculosis Commission an informal meeting of American physicians and hygienists was held in Baltimore on January 28, 1904. The chairman, Dr. Wm. H. Welch, explained the purpose of the convention. A resolution was offered to elect a national committee of two, to represent the American profession at the coming international Congress for Tuberculosis to be held in Paris in 1905. Another speaker requested that it should be decided first what attitude this committee should take regarding the various American congresses for tuberculosis which have been announced from time to time. A lengthy discussion then followed by Drs. Osler, Knopf, Freudenthal, Daniel Lewis, Klebs, Ravenel, Minor, and others. Finally it was decided that a committee should be appointed by the chairman, with full power to act regarding the tuberculosis question and to increase its number if considered necessary. The following gentlemen were then announced as composing the committee: Drs. Osler, Trudeau, Theobald Smith, Adami, Bowditch, Knopf, Klebs, Janeway, Ravenel, Jacobi, Flick, Biggs, and Welch *ex officio*. Besides the above-named there were present Drs. Otis of Boston, Thayer of Baltimore, Health Commissioner Darlington of New York, and many others.

Radiotherapy of Œsophageal Stricture.—It is reported from Vienna that Professor Gussenbauer has relieved a cancerous stricture of the œsophagus by means of radium. A rubber capsule containing sixty milligrams of radium was attached to the end of an œsophageal tube and passed down to the seat of the stricture. After a certain time, which was not definitely stated, in the cabled report, the stricture yielded and the tube passed into the stomach.

Convalescent Home for the Orthopedic Hospital.—Through the benefaction of Miss Emily A. Watson, the New York Orthopedic Hospital will soon open a $100,000 branch at White Plains, which will be both a home for convalescent crippled children and a school for their industrial education. Miss Watson has also promised to endow the new home with a fund of $250,000, so that the entire amount of her gift will be $350,000. The institution will be known as the Country Branch and Industrial School.

Tour of Health Inspection in Mexico.—Early in February a party of health officers from Louisiana and Texas will start on a two weeks' trip on inspection through Mexico. The party will be composed of Drs. Tabor of Texas, Nolte and Owen of Louisiana, and Dr. Souchon, president of the Louisiana State Board of Health. A representative of the Marine Hospital Service will probably complete the party, which expects to investigate quarantine conditions in Mexico, and report upon necessary changes in the rules governing ships from her ports.

The Orleans Parish (La.) Medical Society has received about $900 as a nucleus for the Permanent Domicile Fund. This money was turned over by the Committee of Arrangements for the meeting of the American Medical Association held in New Orleans in 1903. After paying all expenses for the entertainment of the American Medical Association, the committee contributed $650 to the entertainment of the Military Surgeons at the Confederate Reunion, and set aside its balance of about $1600 to promote the founding of a Pasteur Institute in New Orleans during 1903. As the Charity Hospital opened a "Pasteur Institute" department, which cost about $700, the committee paid this expense and turned over the remaining $900 as above.

The Lenval Prize.—It is announced that Baron Léon de Lenval of Nice has given 3000 francs to found a prize to be awarded periodically to the otologist who has made the greatest progress in the practical treatment of the affections of the ear, since the previous award or to the inventor of a portable apparatus susceptible of notably improving the hearing of deaf persons. The value of the prize is the interest on this sum accruing in the interval of two meetings of the International Otological Congress. The prize will be awarded this year at the meeting of the Congress in Bordeaux during the first week in August. Those desiring to compete for the prize should send in their claims before July 1, 1904, to Dr. E. J. Moure, cours du Jardin-Public, 25 bis, Bordeaux, France.

Dr. James T. McKibben of Cincinnati, who has for eight years proved a most efficient district physician, tendered his resignation recently to Health Officer Davis. Dr. McKibben's district comprised the Fourth Ward.

An Osculatory Ship's Doctor.—A man who said he was surgeon on one of the German steamers in port, was arrested early one morning last week for kissing a number of girls as they were coming from a ball in Tammany Hall. After a night in the caboose the lively young practitioner was fined for disorderly conduct and sent back to his ship.

Drainage Canal Fight.—On the final answer by the Supreme Court of the United States to the following questions will rest the result of the suit now pending before that body and in which St. Louis and the State of Missouri seek to enjoin the operation of the drainage canal of Chicago: (1) Has there been an increase of typhoid fever in St. Louis since the opening of the drainage canal? (2) Are typhoid germs able to survive the journey of 357 miles from Chicago to St. Louis, and to enter the intake at Chain of Rocks, Mo.? During the trial of the case to the present time more than ten thousand pages of typewritten testimony have been taken, and the case will probably last three months more, if heard six days each week. It has proven to be the greatest inquiry into water analysis, water supplies of cities, ordinary sanitation, and the study of three large rivers that the world has ever known. Prominent sanitarians, bacteriologists, epidemiologists, and water chemists of the country will appear and give testimony before the court before the closing arguments are heard.

The Canton, Ohio, Medical Society held its annual banquet at the Hotel McKinley on January 8. Dr. Edwin Rickets of Cincinnati was the guest of honor, replying to a toast and reading a paper on "Infection of the Biliary Passages." Other toasts were delivered by Drs. H. P. Pomerene, Harry A. March, and J. F. Kahler. Dr. J. F. Marchand was toastmaster. The officers elected for the ensuing year are: *President*, D. F. Banker; *Vice-president*, E. S. Folk; *Recording Secretary*, C. A. Crane; *Corresponding Secretary*, C. F. Zinninger; *Treasurer*, F. DaHinden; *Censors*, C. E. Schilling, F. W. Cavin, and E. O. Morrow. Guests were present from Cleve-

land, Akron, Alliance, and Massillon. Dr. Rickets was elected an honorary member of the society.

Alumni Association of the College of Physicians and Surgeons.—A smoking concert, under the auspices of this association, will be held at Sherry's, Fifth avenue and Forty-fourth street, Monday, Febuary 8, 1904, at 8.30 P.M. There will be a vaudeville entertainment and supper.

New Children's Hospital.—Mrs. Julia A. Porter has given $75,000 toward the erection of a new hospital in Chicago, which will accommodate sixty children, this hospital to take the place of the present Maurice Porter Hospital. The Maurice Porter Hospital had at first twelve beds, but later thirty-one beds. The new building is to be a modern fireproof structure, and furnished with every facility for the care of six children. The six requirements of the Children's Hospital Association provide for an observation department, where children are kept two weeks before admission to the wards; and isolation department, laboratory facilities, pure milk supply, bedside and didactic instruction for nurses, and one thousand cubic feet of air for each patient.

Antitoxin Plant in Chicago.—It is said that a municipal antitoxin plant will soon be established in Chicago. Dr. Preble, President of the Chicago Medical Society, has urged that the matter be laid before the City Council. Some of the members of the City Council who have been interviewed in regard to the matter have expressed their interest in the establishment of such a plant, and it is believed that something will be done. Dr. Ludwig Hektoen, Secretary of the Memorial Institute for Infectious Diseases, has been authorized to say that if a fund should become available, the institute will furnish space for a laboratory and grounds for stables, provided it is not attempted to furnish serum for any State other than Illinois.

Philadelphia County Medical Society.—At a stated meeting, held January 27, Dr. Orville Horwitz read a paper entitled "A Study of Eighty-nine Cases of Operation for the Relief of Various Forms of Hernia, with Their Complications." Dr. Leon Brinkmann read a paper entitled "Acute Appendicitis: A Review of the Causes for the Delay of Early Operation, and an Attempt to Place the Responsibility for the Continued High Mortality after Operation." He contended that the present mortality of from 4 to 5 per cent. in cases of acute appendicitis should be reduced to one per cent., and that to attain this end operation must be undertaken immediately the diagnosis is made.

Dr. Henry S. Atkins has been appointed Superintendent of the St. Louis Insane Asylum, taking the place of Dr. Edward C. Runge who resigned to enter private practice. Dr. Runge was Superintendent for eight years. Dr. Atkins was born at Lexington, Ky., thirty-six years ago, and graduated in medicine from the Beaumont Medical College (St. Louis) in 1888. For four years he was first assistant of the Eastern Kentucky Hospital for the Insane.

Ohio State Nurses' Association.—Trained nurses from all over the State of Ohio met at the Cincinnati Hospital last week to organize a State society with the object of securing legislation for the advancement of the nursing profession. Registration and State examination laws similar to those governing physicians, dentists, and lawyers are desired. Miss Mary Hamer Greenwood of the Cincinnati Jewish Hospital had the chair. An address of welcome was made by Miss Annie Laws. Dr. Chas. A. L. Reed, Chairman of the Committee on Legislation of the American Medical Association, made an address in which he urged the nurses to organize and promised his support in securing the desired legislation. At a later meeting a State society was formed and the following officers elected: *President*, Miss Mary Hamer Greenwood of Cincinnati; *Vice-Presidents*, Miss Olive Fisher of Cincinnati, Miss Ella Crandall of Dayton, Miss Fannie Wright of Cleveland, and Misses Elizabeth Allen and Doe of Columbus.; *Secretary*, Mrs. Elizabeth M. Hartsock of Cincinnati.

An Embargo on Chicago Hospitals.—Building Commissioner Williams of Chicago has notified those in charge of eight of the smaller hospitals in that city that they must receive no new patients in their institutions until certain specified building changes are made.

The Right to Protect One's Name.—Dr. Ferd. C. Valentine of this city has recently been greatly annoyed by the action of a manufacturing company which made and sold an alleged remedy for gonorrhœa under his name, though with other initials. Neither of the incorporators of the company nor any one connected with it, so far as known, has that name. Dr. Valentine, through his counsel, called upon the company to desist from the use of the name Valentine, and upon their refusal, caused a petition for an injunction against their so doing to be prepared for filing in the Circuit Court of the United States. On January 20, however, the counsel of the company had an interview with his legal adviser, which resulted in the former unequivocally advising his clients to cease using the word Valentine in any manner whatever. In an address to the medical profession Dr. Valentine asks that he be informed in case of any disregard of this advice, in order that he may take steps to uphold his rights.

Crawford County, Ohio, Medical Society.—The Crawford County Medical Society met in Bucyrus, Ohio, on January 27 to discuss topics of interest and to adopt a schedule of fees for the county.

X-ray Prize Essays.—*The Illustrated Review of Physiologic Therapeutics* offers the sum of fifteen hundred dollars in cash prizes for the best essays on *x*-rays in medicine and surgery, the first prize being $1,000.

Obituary Notes.—Dr. GEORGE H. R. BENNET died at his home in Brooklyn on January 24, aged sixty-seven. He was a graduate of the Medical Department of the University of the City of New York in the class of 1860, and was a surgeon in the Twenty-third Regiment in the Civil War.

Dr. GAIUS A. NASH died at his home in this city on January 30, at the age of seventy-eight years. He was graduated from the Medical Department of the University of the City of New York in the class of 1865.

Dr. PHOEBE J. B. WAIT died at her home in this city on January 30 at the age of sixty-six years. She was born in Rhode Island, and was graduated from the New York Medical College and Hospital for Women in 1871, and later held the chair of obstetrics in that institution.

Dr. J. J. A. LIEBENTANZ, a physician of Zurich, Switzerland, died of an overdose of morphine on January 26. He was a passenger on a German steamer which had just arrived at Baltimore, and was on his way to Austin, Tex.

Dr. BRAINARD LEAMAN died at Leaman Place, Lancaster Co., Pa., on January 29 at the age of sixty-two years. He was a surgeon in the United States Army during the Civil War and at one time president of the Lancaster City and County Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CONFISCATION AS A REFORM!—REBUILDING ST. BARTHOLOMEW'S HOSPITAL—READING IN BED—PNEUMOCOCCAL PERITONITIS DISCUSSED—OBITUARY NOTES.

LONDON, January 15, 1904.

MOST people are desirous of preserving any rights they may have acquired even when they do not propose to employ them. But certain busybodies of the British Medical Association propose as a sort of reform to deprive other practitioners of some of their rights to practise. The central division of the London Branch has issued a notice of a meeting to consider the amendment of the medical acts, from which it appears that a member will propose the insertion of clauses in the bill making every registered practitioner eligible to all medical appointments, and, secondly, taking away from registered practitioners their immemorial right to provide and dispense medicines. It is difficult to understand the ideas of so-called reformers who begin by confiscating the rights and privileges of those on whose behalf they profess to act. Think what must be the state of mind of a man who proposes to forbid a fellow practitioner to administer his own remedies under a penalty of "not less than one hundred pounds." Such nonsense reminds one of the superfine fellow of the College of Physicians who let a man die, according to his own opinion, rather than practise surgery by bleeding him. Happily such a confiscating clause is not likely to commend itself to Parliament, but its proposal may well open the eyes of the bulk of the profession to the danger of trusting men incapable of understanding them. Such folly comes of the propensity to regard certain medical work as *infra dig*. Thus we see nurses entrusted with hypodermic syringes, midwives converted into rival practitioners, and numerous instances of duties being shirked. Then comes the young doctor's pride in his position as physician or surgeon, his scorn of the apothecary or general practitioner and the handing over of dispensing to the pharmacist who has long been encroaching on the doctor's work by counter-practice. When every doctor aspires to specialize we need not wonder at the bitter cry of the general practitioner who has to compete with nurses, midwives, chemists, and quacks. But we might have been spared this treachery within our ranks. Let the conceited gent who thinks his fingers too sacred to be soiled with drugs or any remedial agent give up dispensing for his own gratification, but to coerce others to do the same would be intolerable tyranny and decidedly injurious to the public.

The Post Office availed itself of its option to purchase the land of Christ's Hospital which was wanted for St. Bartholomew's, and is not disposed to hand over any part. The rebuilding of old Bart's must, therefore, be otherwise arranged for, and it is pretty well decided that a suggestion I made at the opening of the question will be adopted, which, namely, to remove the nurses' home and other buildings beyond the hospital precincts. Plenty of room for the patients could thus be secured.

Do you read in bed? The practice has been generally decried, and no doubt it has sometimes been the cause of fire. But it is frequently indulged in, and with a varying degree of carefulness. I am afraid doctors are themselves not seldom given to it, though they are ready enough to condemn it in their patients. There is a little discussion on it going on in the press, but not of an enlightening character. That some states of insomnia are aggravated by the habit must be admitted, though others appear to be relieved. I think it is largely a question of the choice of reading and, so far as the danger of fire is concerned, of common-sense precautions.

Pneumococcal peritonitis occupied the Clinical Society at the last meeting. Sir D. Duckworth and Mr. Howard Marsh opened with notes of a case in a woman of twenty-seven, who the day after rigors developed symptoms of general peritonitis; temperature 104.2. Three days later a diagnosis of typhlitis with general peritonitis was made and Mr. Marsh operated. There were signs of inflammation in the peritoneum and large intestine, the appendix, constricted at the base, was dilated above and full of mucus. It was removed. Some thin, dark fluid was found in the cavity; no adhesions; no evidence of perforation. Cultures of this fluid showed the pneumococcus, and inoculation confirmed this. Three days later abdominal pain and hiccough set in. Antipneumococcic serum was tried. Later abscess at the left base formed, leading to resection of part of the ninth rib, when twelve ounces of pus were evacuated and the recovery was steady. The rapid development of grave peritonitis observed in this case resembles what occurs in pneumococcic inflammations elsewhere.

Dr. F. Taylor (President) then related a case admitted to Guy's Hospital under his care last November. The patient was a girl of eight with abdominal tenderness and diminished respiratory movements and physical signs of consolidation at both bases. Laparotomy was performed and pus with masses of lymph removed. The cavity was irrigated with hot saline solution and drained. The right base cleared up, but the left went on to empyema and resection of rib was performed and the pus evacuated. Cultures of the peritoneal pus gave pure growth of pneumococcus, and others from a second collection in the left iliac fossa showed it associated with staphylococcus aureus. Cultures from the pus aspirated from the chest were sterile, but under the microscope showed the badly staining diplococci and empty capsules characteristic of pneumococcic empyema. The child is doing well. Dr. Taylor thought the primary infection was in the lung.

Mr. Stanley Boyd mentioned a case in a woman of twenty-six on whom he operated, removing three pints of pus. Cultures showed pneumococcus. No information as to the primary infection was obtained.

Dr. J. H. Bryant referred to three cases which he recorded in 1901. In these the primary infection was in the peritoneum—a seat he did not consider improbable, as the pneumococcus often invaded healthy throats. Abdominal pain was common in pneumococcal pneumonia, perhaps due to the adhesions between the lung and diaphragm, which we sometimes find after death.

Dr. J. Fawcett said that in one hundred and eighty-two fatal cases of lobar pneumonia in which autopsies had been made only five showed evidence of infection of the peritoneum and that very slight.

Drs. Langdon-Brown mentioned a case of empyema in a girl of ten in whom signs of fluid appeared in the abdomen and right knee-joint, but no operation was performed, as the fluid cleared up. He regarded the case as pneumococcal peritonitis recovering without resort to surgery.

Mr. Golding-Bird remarked that tuberculous appendicitis was recognized and Mr. Marsh's case seemed to justify the further classification.

Dr. J. Eyre said the pneumococcus would be more often found if sought for. He mentioned that the pus from these cases had the curious property, that the upper layers soon became clear, and this might serve as a simple test at the operation, but animal inoculation experiments should be used.

Dr. Herbert French read notes of a fatal case. At the autopsy acute peritonitis with consolidation of one base were found. He divided cases into two groups, one with infection directly into the peritoneum, the other through the blood.

Sir D. Duckworth, in his reply, thought there were varying degrees of virulence of the infection.

Professor Marsh, in reply, said he could not decide if his case were primary appendicitis, but to the list of conditions which may imitate that we must add pneumococcal peritonitis.

The president added that the presence of pneumococci association with another organism was interesting in his case.

Dr. C. E. Saunders, who died on the 3d inst. at Nice, had filled important offices, among them superintendent of the Sussex County Asylum. Prior to that he had been M. O. H. of the district Middlesex and Herts combined. His health failed some four years ago, and he spent the winters in the south of France. He was M.D., Aberdeen; D.P.H., Cambridge; M.R.C.P., London. In earlier days he practised here in London, and is remembered by many as a courteous gentleman of fine presence as well as a sound physician.

The death, at the age of sixty, is announced of Mr. G. E. Legge Pearse, F.R.C.S., late surgeon and lecturer on surgery, and at one time on anatomy, at the Westminster Hospital. Among his contributions were "Two Successful Cases of Ligature of the Common Carotid," and "One of Regnoli's Operation for Removal of the Tongue."

THERAPEUTIC OPTIMISM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Allow me to write that among the unique and valuable features of the MEDICAL RECORD are its letters from foreign correspondents. In your number of January 2, 1904—unless your Auckland correspondent is a victim of therapeutic exhaltation—is a letter of surpassing importance, for it more than hints at the certain cure of three rather common diseases which are usually considered incurable. Such intelligence from New Zealand recalls Macaulay's prophecy as to the future importance of its citizens. This correspondent regrets that so few English-speaking physicians study the action of hypnotism. If the word suggestion is sustituted, it is to be regretted that such is the case, for their is a broad field of usefulness for its employment, particularly in the treat-

ment of women, who, with children, constitute the majority of the average physician's patients.

The Auckland correspondent inveighs with much spleen against the idea that leprosy and cancer cannot be cured. His opportunity for the study and treatment of lepra has been most abundant, covering over thirty-five years. If the leper can be cured, this is a most welcome and important announcement, since our expansion in territory has expanded our responsibilities in pathology. Of lupus, which in its worst form is locally equivalent to cancer, your correspondent writes that "lupus of the very worst kind is invariably cured in four or five weeks by the use of a drug which is in every pharmacopia in the world." This hurts our therapeutic pride, as we cannot even guess the drug which will put an end to the gnawing of the wolf, or the lupus. And it is fervently desired that your veteran correspondent will not be like the native animals of New Zealand, keeping this information, as it were, in a pocket, or like the silent birds in that clime, but that for the sake of those suffering and to suffer from such diseases, and for the sake of his reputation, he will again tell the world the names of the remedies and define the system. Let him not be discouraged.

There will always be doubting Thomases, but we guarantee that their will be belief in the report of the doctor's cases upon the part of a large majority of the readers of the MEDICAL RECORD, and that if he proves that he can invariably cure lupus exedens, a monument will be erected to his memory more enduring than brass.

THOS. R. EVANS, M.D.

DEEPWATER, W. VA.

SHALL THE CONSULTANT DIVIDE FEES WITH THE GENERAL PRACTITIONER?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Under the above caption in the MEDICAL RECORD for January 30, "Specialist" asks, "Would it not be well to obtain some general opinion on this vital subject?"

It seems to me that the question can be settled promptly and easily, on moral grounds. It is proper for the consultant to divide the fee with the general practitioner. If it is worth ten thousand dollars to a man to have his gallstones removed, there is no doubt that the physician who carries the patient through convalescence to fine recovery, the anæsthetist who gives the luxury and safety of modern anæsthesia, the assistants who are chosen because of special fitness for the work, should all share in receiving dignified compensation for their services. There is only one little point to be observed, and that is that the whole transaction must be made with the knowledge of the patient. Otherwise we are guilty of collusion. The physician is a friend to the patient, and does not look upon the latter as his prey. Even among lawyers I find the same spirit prevailing, Horace Greeley to the contrary notwithstanding.

If, on the other hand, the specialist charges a fee for expert work, and gives a part of it to the physician as a sort of commission, the transaction is in the nature of trade, and on analysis will probably be found to have its basis in the idea that the specialist is making a bid for trade, and that the physician is making a confession of weakness in his relation to his patient. So long as the ideals of our profession are ideals of intellect and of character, collusive division of the fee will not occur among men who try to occupy representative positions in the profession. We fight a good deal among ourselves, and say uncomplimentary things, and all that that; but after all we know pretty well who the right men are, and the right general practitioner and the right specialist work together in New York, at least, with single-hearted interest in the welfare of the patient who has reposed confidence in them.

ROBERT T. MORRIS, M. D.

58 WEST FIFTY-SIXTH STREET, NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In answer to letter in the issue of the MEDICAL RECORD for January 30, signed "Specialist," on the question, "Shall the Consultant Divide Fees with the General Practitioner?" I would like to express my views on the subject. These I base on the dictates of conscience rather than on the opinions of those who are solely actuated by motives of self-interest. We all know that in the majority of these cases where the patient is referred to the specialist, the burden of obligation is on the part of the specialist, which should be a state of affairs that all self-respecting men hesitate to assume without making some return as soon as possible.

It is, therefore, the opinion of the writer, and should be also of all who are fair-minded, that it is the duty of the specialist for all cases sent to him to reimburse the general practitioner, who loses his patient, for the time at least, besides for the sacrifice of the patient's confidence. For there is nothing that is less readily pardoned in the physician, on the part of the public, than an admission of inability to treat the case. There is too much of a tendency at the present time to take all we can get and give nothing in return, and of which the question at issue, taken from a negative standpoint, is a most marked exemplification of the case. If we are willing to accept we should not fail to return the favor, otherwise we put ourselves in a position to be characterized only by a term that is applied to a certain animal which our Hebrew brethren most wisely abstain from as an article of diet. In fact too many of us preach "Code of Ethics" and at the same time absolutely ignore the "Golden Rule," two factors which are about as diametrically opposite in their intent, although seemingly the same, as politics and religion are to each other. The former of which provides how others should treat us, while the latter prescribes how we should do to others. Again many of us are prone to lash ourselves into a state of almost frenzy over what we term "commercialism," but when the case is made plain simply demonstrates an inability to make something out of nothing.

We all know that there is no law in any land or a single verse in the Bible that even hints at the prohibition of an act of justice and generosity, such as is exemplified in the case of the specialist reimbusing the general practitioner for the loss of a patient. Parsimony, however, would make such a one. We learn, however, from the Bible that "Charity covers a multitude of sins!"

Therefore let us endeavor to purify our motives at all times, which is a state of affairs that can never be if we are forever thinking of dollars and cents.

PERRY DICKIE, M.D.

17 SCHERMERHORN STREET, BROOKLYN, N. Y

Progress of Medical Science.

The Boston Medical and Surgical Journal, Jan. 28, 1904.

Experiments with the McGraw Elastic Ligature.—Fred. T. Murphy concludes, from his experiments on animals, that a successful anastomosis between the stomach and intestines, or two loops of intestine, is possible by means of the elastic ligature. The method is not applicable when an immediate opening is required. The time of the cut-out varies, depending upon the character of the ligature, the method of application, and the resistance of the tissues in any case, but the ligature will ultimately cut out. A knot at either end of the elastic loop increases the rapidity of the cut-out. The pinching of the gut by the ligature seems to cause no bad symptoms. The serous surface of the outside of the joint when completed is smooth. The anastomosis by gross or microscopical examination shows no evidence why there should be any greater tendency to contraction of the opening than with the ordinary methods of intestinal suture. The procedure causes a minimum operative risk, both as regards shock and infection. Adhesions across the opening are a possible, but not a probable, complication. The writer believes that in cases in which an immediate opening of the bowel is not imperative, and in which the avoidance of operative shock is an important factor, the elastic ligature may prove to be the operation of choice in gastroenterostomy and lateral anastomosis.

Differential Diagnosis of Rheumatism and the Arthritides.—Thomas F. Harrington states that rheumatism and arthritis are not synonymous terms. The characteristic symptom of rheumatism is an arthritis, but there are many arthritides which cannot be associated with rheumatism as clinically accepted. No case of arthritis should be considered rheumatic unless an undisputed attack of acute rheumatism can be given. Rarely is rheumatism diagnosed other than it is; the danger lies wholly in the opposite direction. There is probably but one form of rheumatism, namely acute rheumatism. The writer then suggests the following classes of arthritis: Infective arthritis, arthritis deformans, osteoarthritis, traumatic arthritis, gouty arthritis, hæmophilic arthritis and senile arthritis. Idiopathic arthritis probably never occurs. In infective arthritis there is usually a history of a primary infection to which the arthritis is secondary. Arthritis deformans closely resembles rheumatism in its acute stage, and may occur in combination with acute rheumatism, but it is not caused by rheumatism. It is non-inflammatory and may occur without pain. There is seldom redness or tenderness. It is rarely monarticular, and it never suppurates. It is probably due to some nerve disturbance. Osteoarthritis may result from many causes. It may start without any known cause. It is essentially a chronic disease. In traumatic arthritis, the history of the case is important. There is usually water in the joint in traumatic cases. The character-

istics of gouty arthritis are sudden onset, especially at night, often disappearing in the daytime, also the presence of deposits in the ear (tophi). It attacks usually single small joints. Hæmophilic arthritis usually occurs between the fourth and sixth years and most often in males. The joints affected are knee, 50 per cent.; elbow, 25 per cent. In senile arthritis there is a thickening of the capsule, but not of the bones. It has no relation to rheumatism and is more stiffness than soreness. It does not involve the heart and grows better as the day progresses. In children the family history, or a history of "growing pains," especially if accompanied with even slight swelling (fibrous nodules), suggests rheumatism.

Journal of the American Medical Association, Jan. 30, 1904.

Pathology of the Cervical Sympathetic.—J. E. Weeks enumerates the various abnormal conditions following: First, irritation and, second, paralysis of the sympathetic. He does not believe that the testimony in our possession enables us to say that there is any constant change in the cervical sympathetic peculiar to glaucoma, or to exophthalmic goiter. In the aged these ganglia undergo degeneration to some extent. Changes also occur in constitutional syphilis, leukæmia, pellagra, tuberculosis, and infectious diseases. These changes are variously of the nature of either atrophy-hyperæmia, sclerosis, pigmentary and fatty infiltration, amyloid degeneration or accumulation of colorless blood cells and micrococci in the blood-vessels of the ganglia. Brief allusions are made by the author to some of the more interesting cases of lesions of the cervical sympathetic recorded in literature.

Pathology of Inebriety.—T. D. Crothers offers the following conclusions: (1) In all cases of inebriety there are marked changes in the capillary and vascular system of the brain. The walls of the vessels show fibrinous deposits and sclerosis. The nerve cells and dentrites are altered and retracted, in some cases permanently destroyed; in all inebriates shrunken and disintegrated states exist. (2) The liver, kidneys, and heart show diminution or enlargement with fibrous and fatty deposits. Both the organic and functional activity of the organ are changed and sclerotic states are present. Conditions of starvation and poisoning exist in all cases. (3) Pathologic changes are apparent in the paralysis of the sense organs and the higher psychic functions of the brain. These conditions are so common following the use of alcohol, sometimes in its moderate use, but always when taken in excess, as to constitute a pathology that is traced directly to alcohol as the most prominent cause. (4) The recent researches into the chemicophysiologic action of alcohol on the heart, blood-vessels, cells, and nerve fibers show a paralyzing and eroding action that cannot be mistaken for any other cause. The final conclusion is that the peculiar brain and nerve wreckage so commonly seen in persons using alcohol is due to the specific cause, alcohol following a uniform line of degeneration which is traceable with more or less exactness.

The Treatment of Emotional Disturbances.—H. T. Pershing lays down the following general rules of treatment: (1) The idea exciting the undesirable emotion should, as far as possible, be removed and replaced by ideas of an opposite tendency, as when a patient who is frightened and depressed by the idea that he has heart disease is thoroughly examined and positively assured that his heart is perfect. (2) The motor reaction characteristic of the emotion should, as far as possible, be voluntarily suppressed and replaced by the motions and demeanor characteristic of the opposite emotion, as when a patient threatened with a hysterical spell forces himself to breathe deeply and slowly, relaxes the muscles and assumes a calm demeanor. (3) An exhausted and irritable nervous system must be rested, built up and soothed so as to make it less susceptible to emotional storms: (4) Poisons which irritate and depress must be eliminated, as in the so-called uric-acid diathesis, uræmia, diabetes, alcoholism, etc. (5) A diseased organ which sends abnormal sensory impulses to the cortex and thus causes the feeling of fear or of grief without such mental cause as would otherwise be necessary, must receive appropriate treatment, as in certain cases of disease of the heart, stomach, liver, intestinal canal, or pelvic organs. (6) Other means proving inadequate, a painful emotion may be controlled by full doses of opium, as in the opium treatment of melancholia.

Medical News, January 30, 1904.

A Brief Note on the X-ray Treatment of Glandular Tuberculosis.—Frank P. Vale reports this case. The patient was a man who had never been ill till the present sickness, which began about six months before he came to the writer. A slight swelling first appeared on the left side of his neck. It had increased slowly in size and the patient had progressively lost weight. The writer exposed the affected side of the neck to the *x*-rays twice a week for fifteen to twenty minutes. The patient rapidly improved. During two weeks he had gained fifteen pounds, and during the next four weeks he almost entirely regained his normal feeling of well-being and strength. The swelling in the neck was greatly reduced. In order to prove the nature of the lesion in the glands, operation was performed and microscopical examination made of the parts removed. This histological picture was that of tuberculosis. The patient remained in good health for about a year when symptoms developed which pointed to an intracranial lesion. Improvement at the end of a month of renewed *x*-ray treatment—exposing the head to the rays three times a week—has been most satisfactory.

A New Method for Performing Intestinal Anastomosis.—John W. Keefe describes his method of performing intestinal anastomosis as follows: The intestine to be excised is clamped at a right angle to its long axis with a ¾-inch blade of the electrothermic angiotribe; a current of 60 ampères is applied for one minute. In this way complete hæmostasis, with occlusion of the gut, is produced, with no extrusion of fæces. The angiotribe is removed and the desiccated strip of intestine is clamped with a straight artery forceps. The same process is repeated at the other point on the intestine where it is to be severed. Incision is made. The mesentery attached to the partly excised part of the intestine, is clamped with the angiotribe, and the current applied, in as many sections as is necessary. The mesentery is separated and the excised part of the intestine is removed. The desiccated ends are now approximated and their peritoneal surfaces united with a modified and an interrupted Lembert suture. The modified suture is first inserted. The interrupted Lembert suture is inserted at opposite poles on the intestine to the stitch previously made. In placing the two Lembert sutures and the Cushing suture, the main point to remember is not to penetrate the mucous coat of the intestine but to have it enter the submucous coat, since it is tough and fibrous. After the edges of the intestine are sutured, the intestine is invaginated with the finger and sufficient force is used to make a lumen through the desiccated strip. Gases and fæces are pressed through the anastomosed ends to see that there is no leakage. The writer sums up the advantages of this method as perfect asepsis, no intestinal obstruction, no eversion of mucous membrane, little danger of cicatricial stenosis, a firm, strong union, and a rapid operation.

New York Medical Journal, January 30, 1904.

Solitary or Fused Kidney.—W. A. Dennis reports one case and discusses various aspects of the question. His paper is summarized as follows: (1) Complete absence of the kidney is found once in 2,650 cases, the horseshoe shape once in 1,000 cases, and the fused kidney (exclusive of the horseshoe variety), once in 16,000 cases. (2) The majority of fused kidneys are misplaced, being usually abnormally low and in the median line. (3) The completely fused kidney with normal position and approximately normal outline is the rarest of all. (4) Cystoscopic examination with catheterization of the ureters will prevent the error of removing the only organ present in all cases except those of fusion. (5) Horseshoe and irregularly fused kidneys may be recognized on exposure by their abnormal shape and position. (6) The single remaining and rarest variety (that with normal outline and position can probably always be at least suspected if the ureter and pelvis are found shifted to the anterior surface.

Purulent Pericarditis Secondary to Pneumonia, with Operation and Recovery.—The patient of J. A. Scott was an Italian laborer, thirty-six years, with consolidation at first the right base and later the left. Later the pericardial sac became involved, and the needle withdrew a light-greenish turbid fluid, showing a pure culture of pneumococci. Aspiration removed fourteen ounces of such fluid (1016 albumin 2 per cent.), but it reaccumulated and further exploration revealed pus. The pericardial sac was opened under cocaine anæsthesia (the patient doing badly under chloroform and was slowly drained), about twenty-four ounces of non-odorous pus coming away. Recovery was without especial incident. Peculiar features of the case were: (1) The absence of a leucocytosis during the pneumonia, and its development with the pericarditis. (2) The absence of the pericardial friction both before and after the pericardium was opened. (3) The absence of fever—subnormal temperature—with pus in the pericardium. (4) The recovery of the patient without the physical signs of an adhesive pericarditis, no pericardial friction sounds being heard.

American Medicine, January 30, 1904.

Unpublished Symptoms of Rötheln.—J. D. Maddox reports that in an epidemic of rötheln or German measles

now under observation, he notices two symptoms which have so far been constant in every case. He does not find these symptoms mentioned by any authority that he has consulted. They are: a bloody discharge from the nose as if produced by rupture of the engorged capillaries; and soreness, stiffness and swelling of the fingers, soreness and sometimes stiffness of the wrists, elbows and knees, and less frequently of the ankles, as if there were present transient inflammation of the synovial membranes. In some cases there seems to be the same conditions present in the sheaths of some of the tendons.

Postoperative Intestinal Obstruction.—A. M. Pond states that intestinal obstruction occurs as a complication in about 5 per cent. of all abdominal operations. Its natural classification as to cause is as follows: (1) Impairment of physiologic function; (*a*) impaction, (*b*) paresis, or disturbance of motor nerves, (*c*) lowered resistance following hemorrhage, (*d*) atony from alcoholism, diabetes, etc. (2) Pathologic processes, such as (*a*) inflammatory impairment of function, (*b*) destruction of parietal peritoneum, (*c*) intoxication by pus, (*d*) thrombosis of mesenteric veins, following contusion. (3) Mechanical obstruction due to (*a*) adhesions to stumps improperly covered, (*b*) velamentous or adventitious bands arising from the parietal peritoneum, (*c*) omental rents or tears, (*d*) accidents to the sutured wall, (*e*) presence of gauze sponges or other foreign material accidentally left in the cavity after the operation. It can be easily seen from the foregoing, that the treatment of postoperative obstruction depends very largely upon its cause. In cases due to impairment of physiologic function, stimulation of peristalsis should be the object aimed at, and it will probably respond to any medication that will secure such stimulation. An enema, medicated or plain, is by far the simplest treatment and the easiest of administration. If it does not prove effectual, the application of the cautery over the abdomen should be tried. The use of cathartics is very questionable, since the nerves which stimulate peristalsis are already impaired and will not readily respond, and when they do, it is at the expense of more energy. Increased medication is required to secure each succeeding evacuation. Rest is valuable, and if the patient is doing well aside from the bowel movements, too much energy should not be excited in order to secure evacuation. In cases due to pathologic processes, cathartics are positively counterindicated. Treatment should consist in lessening the peristalsis and securing rest. The sedative action of atropine in all spasmodic conditions stands second only to opium, and it is superior to the latter drug in that it is not constipating. It dilates the blood-vessels and relieves stasis and congestion. The use of oxygen is valuable since it lessens the formation of ptomains and albumoses by supplying the congested blood-current with its vitalizing element, the same as it would receive from the inspired air through the pulmonary circulation. In mechanical obstruction the only rational mode of treatment is to release the intestine. This can be accomplished only by operation. The earlier this operation, the more favorable will be the prognosis.

The Lancet, January 16, 1904.

Physiological or Functional Albuminuria.—The conclusions of Samuel West are as follows: (1) Albuminuria may occur as a transitory symptom in persons who, except for this symptom, may be judged to be perfectly healthy, for they appear to be so at the time and remain so. (2) But it may also occur in persons who, though they appear at the time to be healthy develop signs of disease subsequently. (3) It is difficult to distinguish at a given time between those who will remain well and those who will not. (4) It is difficult to exclude for certain many of the pathological causes to which the albumin might be due. In other words, though there may be no proof that these causes are present, there is equally no proof that they are absent, and in some cases, the result shows that they were not absent. (5) Speaking generally, the larger the amount of albumin in the urine and the longer it persists the greater the probability of some permanent disease. (6) Continued observation of these cases shows that the so-called physiological albuminuria does very appreciably increase the risk of life, and that this risk grows rapidly with every year of age after thirty years. As a result of the foregoing proposition, the author is led to the general conclusion that functional albuminuria is never, strictly speaking, physiological at all, but that it is, on the contrary, always pathological though not necessarily renal.

The Termination of a Case of Recurrent Mammary Cancer Treated by Oophorectomy.—The history of the case is given by G. E. Herman. The original cancer was removed in 1890. Six years later it had recurred and invaded the axilla and neck, so that removal of the recurrent growths was impossible. Three months later the ovaries were removed, and the patient remained in good health for over four years. Evidences of cancer of some internal organ then appeared, and she gradually succumbed. The author justifies the performance of oophorectomy in such cases on the following grounds: (1) The immediate risk to life is small; (2) the suffering caused by the operation is but temporary, and (3) the effect of ovariotomy on certain functions is for the patient's good. On the other hand, a reasonably certain promise can be given the patient that her life will be prolonged for some months, and possibly for some years.

Some Forms of Chronic Abdominal Surgical Disease.—E. S. Bishop notes that such diseases are found especially in connection with the digestive tract, either in this alone or in connection with the liver and pancreas, and the excretory ducts of the latter. Infective material in the biliary passages may cause cholecystitis leading to suppuration, empyema of the gall-bladder, and gangrene, or it may produce hemorrhagic pancreatitis. Sloughing and abscess. Such infective material may lead to or lodge in biliary calculi, which thus become the more direct cause of trouble, various tumors of the gall-bladder and especially cancer may follow. This is another argument for the removal of calculi as soon as they give demonstrable symptoms and can be definitely located. Another large class of abdominal complaints is comprised of those affecting the large intestine. Peristalsis does not occur here under the conditions obtaining in the smaller bowel. To use the author's phraseology, "the small intestine with the stomach is the kitchen which pours its refuse into the slopstone and drain of the cæcum and colon. Most morbid conditions affecting the large intestine are mainly chronic in character, and extend in their whole course over long intervals of time, although many of them signalize their presence only when pathological changes have reached a certain stage, after which their further progress may be much more rapid. A condition of difficult and painful defecation should always draw attention to the anus and rectum. Some cases of obscure pain in the latter may be puzzling. An ulcer may exist on Morgagni's valve, and for a long time elude detection. Hence in all obscure cases a complete rectal exploration is necessary. The sigmoid flexure is a favorite seat for cylindroma. The treatment of mucocolitis, in its many forms with and without ulceration, which may be specific, gonorrhœal, simple, lupoid, herpetic, dysenteric, or cancerous, has been greatly assisted by the clearer ideas which have been gained of the actual condition of the interior of the gut since the more thorough use of the proctoscope and sigmoidoscope; the newer silver salts, especially protargol, have supplied us with agents which are not rendered ineffective by the rapid formation of an inert albuminate, as was the case with the older nitrate, but permit of far deeper and further reaching action upon the tissues and the microorganisms which have penetrated them. The author dwells, in closing, on the necessity for constant observation of chronic cases with a view to the discovery, if possible of new symptoms which will throw light upon their earlier stages, and which may act as danger signals, so that effective surgical interference may be carried out whilst there is every reason to expect a successful issue and before dangerous complications have arisen, or at least before they have reached such a stage as to render all our efforts ineffectual.

British Medical Journal, January 16, 1904.

A Note on the Tendon Reflexes in Uræmia.—W. Mitchell Stevens is convinced from the examination of a considerable number of cases that an exaggeration of reflex activity is often present in cases of uræmia. The condition may show itself not only by an exaggeration of the knee-jerks, but in severe cases such phenomena as ankle-clonus, knee-clonus, wrist-jerk, and elbow-jerk may all be present and well marked. The writer does not assert that the reflexes are constantly excessive in cases of uræmia. Nevertheless, this symptom is common, and it may prove of diagnostic value in comatose states and in certain convulsive affections, such as the epileptiform convulsions of uræmia. In a case of this kind, the presence of exaggeration of the deep reflexes might be helpful.

Chronic Cyanotic Polycythæmia with Enlarged Spleen.—William Osler suggests to those who meet with cases of chronic cyanosis with polycythæmia, to study carefully the condition of the heart and lungs, and in the blood the specific gravity and the viscosity, as the cyanosis probably depends upon the latter and upon the increased difficulty in the flow of the blood through the capillaries. The writer adds several cases to those which he has previously reported. The chief symptoms of this condition are constipation, headache, vertigo, and weakness. In some cases the patients were in very good health, in spite of an intense cyanosis. The cyanosis is the most remarkable feature of this affection. There is, as a rule, no respiratory distress, nor any obvious cause for this condition. The blood in the cases reported presented a greatly increased viscidity, an unusually dark color, and

in eight of the cases the red-blood corpuscles were above nine millions per cubic centimeter. The hæmoglobin ranged from 120 to 150; the leucocytes showed no special changes. In the study of obscure cyanosis, the writer states that it is well to bear in mind the possibility of chronic poisoning with the coal-tar products.

A Lecture on Lumbago; Its Lessons and Analogues.—William R. Gowers declares that although we have a sufficiently clear and precise conception of the symptoms of lumbago, our conception of its nature is not at all precise or clear. Lumbago is correctly regarded as muscular rheumatism. Lumbago in particular, and muscular rheumatism in general, are a form of inflammation of the fibrous tissue of the muscles. The writer designates this affection as "fibrositis." Although there is no indication of the formation of "inflammatory products," lumbago has the acute course of an inflammation and may result from a frequent cause of this in any part—exposure to cold. Its symptoms appear to develop with extreme suddenness. The writer believes this to be apparent and not real. The production of the pair is sudden, but the condition upon which it depends has been gradually developed. This process varies considerably according to its cause and seat. Apart from the muscles and tendons, the fibrous tissue of the joints is liable to a condition in which tension causes acute pain. The writer then discusses brachial myalgia. Its great feature is pain in the muscles. Any attempt at passive movement causes extreme pain. This brachial fibrositis may spread just as sometimes does the lumbosacral form. For "sacral lumbago" often spreads, apparently by the fasciæ, and reaches the sheath of the sciatic nerve. There it may increase to definite sciatic neuritis. In the brachial form the fibrositis may reach the nerve sheaths of the arm, and in them set up a secondary brachial neuritis with all its consequences, tenderness of the nerves, pain along their course and in their distribution, œdema of the hand, and even muscular wasting or impaired sensation. Rheumatic fibrositis is seldom strictly symmetrical. Muscular rheumatism is more common in the second half of life than in the first, while the opposite is true of the acute articular form. It is currently associated with gout, but it is "gout with a difference." Another definite form of fibrositis is the traumatic, induced by sudden violent tension on tendinous and ligamentous structures, much less frequently by tension on the muscles. In discussing the general treatment of these forms of rheumatic fibrositis, the writer calls special attention to the measures of diaphoresis and rest. Above all things, rest is that which these painful muscles need.

Deutsche medizinische Wochenschrift, January 7, 1904.

Musical Heart Murmurs.—Galli reviews the theories that have been advanced to explain the musical or metallic murmurs sometimes heard, and describes a case of his own in which the relation between cause and effect seems very plain. The patient was a man of fifty who, after a more or less complicated illness died, of multiple pulmonary infarctions. During life a systolic, musical murmur was heard at the apex and part way to base, and sometimes, but not always, faintly over the aorta. It was never present over the pulmonary area. The murmur was accompanied by a pronounced thrill. On autopsy, in addition to various irrelevant lesions, an intraventricular band was found running from the anterior papillary muscle toward the apex and having a sufficient space under its arch to permit a considerable volume of blood to flow under it. A point of interest is that for a day or two before death the musical murmur disappeared, and it was found that an ante-mortem clot had formed about the base of the adventitious band, thus preventing it from vibrating.

Further Observations on the Preparation of Specific Substances from Bacteria.—Mayer describes several methods of extracting substances from cholera bacilli which produce strongly bactericidal sera in experiment animals. One method is analogous to that employed by the author for typhoid bacilli, and consists in macerating the organisms for eight days in ammonium sulphate solution. The fluid is filtered and the bacterial mass remaining on the filter is washed off, rendered faintly alkaline, and subjected to autolysis at a temperature of 37°C. In about three days the process is complete, and the result is a tenacious, almost gelatinous fluid in which no bacterial bodies are demonstrable. By injecting this into rabbits, sera are obtained which have a high bactericidal but low agglutinating titer, while exactly the reverse is true for typhoid bacilli. It was found that by simply shaking cultures of cholera bacilli in a machine for six and for forty-eight hours, substances were extracted from the bacteria by this purely physical process which produced sera of fairly high bactericidal value.

The Pathology and Treatment of Cardiospasm.—Mikulicz believes that the so-called idiopathic dilatation of the œsophagus is the result of spasm of the cardia. In order to understand the development of the condition it is necessary to consider the mechanism of deglutition. This differs essentially for fluids and solids. The former overcome the normal tonic contraction of the sphincter-like cardia solely through the effect of gravity, while solids are forced onward by peristaltic contractions of the œsophagus. If the natural tension of the cardia is increased, fluids no longer can leave the œsophagus freely, and a column of fluid remains in its lower part. Gradually dilatation follows and, once started, increases rapidly, as a larger surface is exposed to pressure and atony of the muscular layer is produced. Now solids also remain in the œsophagus, for its walls can no longer contract firmly over them in the dilated portion, so that fermentation is induced and œsophagitis is set up by the presence of the irritating food masses. A vicious circle results, the cardiospasm causing stagnation, this giving rise to œsophagitis, which, in turn, increases the spasm. Palliative treatment by diet, lavage of the dilated œsophagus, etc., often accomplishes much, but the author has had perfect results in four cases after instrumental dilatation of the cardia through a gastrotomy incision. The degree of dilatation can be perfectly controlled by touch so that there is no danger of rupture, and the patients have been completely cured.

Deutsche medizinische Wochenschrift, January 14, 1904.

The Neutrophile Leucocytes in Infectious Diseases.—Arneth gives in generalities the results of investigations he has been pursuing regarding the polymorphonuclear neutrophile leucocytes; the details are to appear in book form. The aim of his communication is to point out that although a great deal of blood counting has been done, the advances of the past few years have been very slight. The information to be gained by enumerating the leucocytes and making differential counts of their various types has reached its limit, and he has opened a new field for study by analyzing the class we have heretofore considered as an entity and termed the polynuclear neutrophiles. By special methods he has found typical and consistent variations in the nuclei of these cells, and has constructed a classification composed of five variants. In normal, hyper- or hypoleucocytosis many variations of proportion among these five classes occur and the author proposes the following terms to be used accordingly, as the neutrophilic blood picture agrees with or varies from the normal: (1) Hypercytosis; (*a*) isohypercytosis, (*b*) anisohypercytosis. (2) Normocytosis, (*a*) isonormocytosis, (*b*) anisonormocytosis. (3) Hypocytosis, (*a*) isohypocytosis, (*b*) anisohypocytosis. As is to be expected, such considerations lead to speculations in the fields of chemotaxis, antitoxin formation, immunity, the genealogy of the leucocytes, etc., but these are too general in nature to be susceptible of abstract in brief, and their value can hardly be judged of till the complete work with details and statistics appears.

The Physiological Action of the Radium Rays and Their Therapeutic Application.—Scholtz has been experimenting with radium on animals and on patients and finds that its rays have certain properties in common with the *x*-rays and the Finsen rays and that they also differ from them in certain respects. While the general effect of radium rays on the skin resembles that of the *x*-rays and overexposure produces similar lesions, important gross and microscopical differences are noted. The visible changes produced by the *x*-rays usually appear only after the fourteenth day, but the radium rays cause a pronounced erythema in about twenty hours, even after an exposure of only three to five minutes. In sections made at this time a dilatation of the vessels of the papillary layer is visible, and on the third or fourth day there is slight swelling of the connective tissue. The *x*-rays produce no changes to be detected by the microscope so soon after the exposure. In order to test the penetrating power of the rays the author fastened the ears of a rabbit one over the other on the animal's back and then exposed them to the radium for fifteen to thirty minutes. A marked reaction was produced in both ears and the skin of the back became inflamed and lost its hair. Bacteria are killed by the rays both in agar plates and suspended in fluids. With the radium at a distance of two mm. typhoid bacilli were killed in three hours. The author's therapeutic results on cases of furunculosis, lupus, psoriasis, and epithelioma are very encouraging, two cases of the latter appearing to have been permanently cured. The great advantage of the radium is the ease with which the substance can be applied to otherwise inaccessible regions, such as cavities like those of the mouth, vagina, nose, etc., and even the interior of tumors.

Berliner klinische Wochenschrift, January 11, 1904.

The Methods for Determining the Boundaries of the Heart.—Rosenfeld reviews the various methods which have been employed to establish the size of the heart by percussion. The much-discussed question as to whether

the absolute (superficial) or the relative (deep) dulness is a more reliable index of the condition present seems finally to have been summed up by the dictum that the absolute dulness is easier to determine, but that the relative dulness gives a more accurate picture of the cardiac dimensions. The author employs the palpatory percussion of Ebstein, performed with a special hammer and plessimeter. His technique is first to determine the absolute dulness by finger percussion, performed as gently as possible, and then to obtain the true dimensions of the heart by palpatory percussion. In both instances it is preferable to proceed from the center of greatest dulness toward the periphery. Other methods that are less satisfactory are the auscultatory percussion of Ewald and Runeberg, the friction auscultation of Reichmann and Bianchi, and the method similar to the latter employed by Smith with the phonendoscope.

Expulsion of a Tubular Cast of the Œsophagus after Poisoning with Muriatic Acid.—Strauss reports this case, which belongs to the rarities of medicine, inasmuch as only one other has been described. The patient was a middle-aged man of tuberculous history and poor general condition. Twenty-five c.c. of hydrochloric acid were swallowed, and shortly afterward he came under observation. The treatment consisted in lavage with soap solution, and after that calcined magnesia and rectal feeding. On the ninth day in bringing up a quantity of brownish secretion, which had been very abundant from the first, the patient expelled a tubular cast of œsophagus twenty-three cm. long. This apparently was the mucous membrane which had separated in the submucous layer. From this time on small amounts of fluid were given by mouth and fairly rapid improvement followed. About two months after the poisoning, however, he began to do poorly again, and died a little over a month later of malnutrition. The autopsy showed that the œsophagus was not stenosed, but that it was entirely devoid of mucous membrane for most of its length, and that the stomach was the seat of a diffuse thickening, which was so marked at the pylorus as to give rise to a true stenosis. The dissection of the mucosa from the underlying structures is supposed to have been the result of an inflammatory necrosis due to suppuration along this line, and the thickening of the stomach due to a general sclerosis starting from a multitude of minute scars. About a dozen cases of the expulsion of similar casts have been described, but these have been after the ingestion of sulphuric acid or strong alkalies. Probably the occurrence is more frequent than supposed, as the mucous membrane is easily overlooked in the vomitus.

Münchener medizinische Wochenschrift January 5, 1904.

The Staphylococci of Chronic Eczema.—Veiel studied the microorganisms of chronic eczema in order to determine their nature, whether they were purely saprophytes or not, and what relation they had to the etiology of the disease. He found that both in the early and late stages of the disease staphylococci were found almost exclusively. These were identical with the ordinary pus producers and could be distinguished from those of the ordinary skin by agglutination and hæmolytic reactions. Their importance in regard to the etiology of the disease is still undetermined, but it is not likely that they are pure saprophytes, and probably they are concerned in some way in the causation of the pathological processes. No other bacteria, however, were present in the early stages, so that the existence of any specific organism is not likely.

Modern Theories of Eclampsia.—Wormer has repeated the experiments of various investigators who have published results tending to show that eclampsia is due to some form of cytolytic poisoning. Veit found that the serum of animals that had received injections of placental tissues from some other species possessed the property of dissolving placental cells of the same sort *in vitro*. He concludes that eclampsia is a direct poisoning of the mother's blood through fetal substances which enter it and are not neutralized with sufficient promptitude. Ascoli injected rabbits with guinea-pig placenta, and so produced a serum containing a syncytiolysin specific for guinea-pig placenta. On injecting this serum subdurally into guinea-pigs, they died with eclamptiform manifestations. Ascoli's theory is that the excess of syncytiolysin resulting from overproduction is the toxic agent. Weichardt treated placental tissues with a specific serum until solution took place and then injected it into animals. Out of nine three died under conditions comparable to eclampsia, and he believes that syncytiolysis gives rise to free syncytiotoxins which are the cause of eclampsia. Liepmann obtained a serum giving a precipitin reaction specific for placental tissue by injecting animals with placenta of the same species. The author repeated the experiments of all these authors with much attention to detail, but failed entirely to get the same results in any set of observations.

The Toxins and Antitoxins of Fatigue.—Weichardt experimented with mice to determine the nature of the substances formed during fatigue. At first he injected the blood of the fatigued animals into other mice intraperitoneally, but these did not die any oftener than did control animals injected with the blood of normal mice. Attempts with intravenous and subcutaneous injections were equally unsatisfactory, and it seemed most likely that either no toxins at all were formed or else that they were very quickly taken up by the antitoxins of the blood and so lost their virulence. Acting on the latter hypothesis, he made muscle extracts from the fatigued animals under rigid asepsis, and then found that the extract from fatigued animals was toxic, while that from others was not. The toxins so produced are thermolabil, and are rendered inactive by an exposure of two hours to 56° C. During the first forty-eight hours their toxicity increased, but then diminished, and at the end of eight days had vanished completely. This gradual increase in toxicity leads the author to believe that the products of fatigue are at first not true toxins, but become so as a result of fermentative changes produced by the body juices. By injecting rabbits with this toxin an antitoxin was produced of very stable nature and capable of neutralizing the toxin both in the body and in the test tube.

Münchener medizinische Wochenschrift, January 12, 1904.

A Case of Indigo Red in the Freshly Voided Urine.—Gröber reports this unusual phenomenon, which occurred three months before the death of a fourteen-year-old girl, who was suffering from advanced chronic parenchymatous nephritis and mitral stenosis with broken compensation. The urine which had been very pale, suddenly showed a deep pink color. The examination showed the absence of indican, while the coloring matter could be extracted by the addition of chloroform without the intervention of any reducing reagents. Indigo blue or red is not a rarity in urine that has undergone decomposition, but in this case it was present in the freshly voided urine.

The Anterior and Posterior Divisions of the Urethra, and Urethral Injections.—Lucke says that the prevalent view that the anterior urethra is separated from the posterior by a competent sphincter, the compressor urethræ, is open to criticism, and has produced errors of treatment. Individuals vary greatly in the tonicity of the cut-off muscle, and the practice of injecting comparatively large quantities of fluid into the anterior urethra with the idea of distending all the folds of the mucosa and reaching the gonococci hidden there, is a frequent cause of posterior urethritis. The anterior urethra is usually kept distended with the injection for about five minutes, and during this time the cut-off muscle relaxes and allows the infection to invade the posterior urethra. The proof of this is found in the frequency with which posterior urethritis is observed nowadays, whereas it was much rarer under the old régime of syringes, with small pointed nozzles and of small capacity. A positive two-glass test is evidence of the existence of posterior urethritis, even in the absence of increased frequency of micturition, and conversely the infection may have gone posterior and the two-glass test be negative.

The Treatment of Gastric Ulcer.—Wagner recounts the results obtained on a large series of patients treated for gastric ulcer by Lenhartz's method. This consists in dispensing entirely with the customary nutritive enemata and in giving the patients raw eggs as adjuncts to the milk diet from the very first. The idea is that most of these patients, particularly those that have had hemorrhages, are likely to be more or less anæmic and of poor vitality, so that to put such individuals on a starvation diet is to furnish the least favorable conditions for the reparative effort which is to heal the ulcer. The patients are kept in bed four weeks, an ice-bag over the stomach being used to combat pain and promote contraction of the organ. In the first twenty-four hours iced milk is given in spoonfuls up to 200-300 c.c. and from one to three iced, beaten, raw eggs are allowed. Two grams of subnitrate of bismuth are given two or three times a day. The amount of milk is daily increased by 100 c.c. up to one liter, and one egg a day is added until six or eight are being taken. On the sixth day 35 g. of finely scraped raw beef are given, and the dietary is rapidly extended until it comprises rice, gruel, milk toast, and at the end of three to four weeks, a mixed diet including cooked meat. The histories of sixty cases are appended in brief and show most satisfactory results, fifty-two of the number being discharged cured within two months of treatment.

French and Italian Journals.

Radiotherapy and Cancer.—Tuffier has two patients suffering from cancer of the face whom he is treating by the *x*-rays. In one of these cases the lesions are evidently undergoing improvement. Tuffier thinks that perchance

radiotherapy will render good service in the case of superficial cancer. As to its influence on visceral cancers he is not so certain.—*La Presse Médicale*, December 5, 1903.

The Use of Catgut Prepared after the Method of Claudius.—Giuseppe Coen thinks that this iodized catgut cannot be praised too highly. He tried it in fifty important operations. Three of these patients died—one after cæsarean section, one after Talma's operation for cirrhosis of the liver, and the third after vaginal hysterectomy on the twenty-second day following operation from pyelonephritis. Death in all the cases was entirely independent of the sutures. The remaining thirty-seven cases went on to recovery. The rise of temprature did not go above 99.5°, and the cicatrization took place entirely by first intention.—*Archivio di Ostetricia e Ginecologia.*

Arthropathy of Syringomyelia.—Prof. E. Bressaud thinks that in a case of double arthritic disease with rapid destruction, but no pain and preservation of function, there is probably an organic lesion of the cord. The spinal origin of such affections is practically certain. The differentiation of tabes and syringomyelia is more difficult. The major symptoms of both conditions are alike; the only diagnostic difference lies in the minor and transitory symptoms of the initial stage of this slowly progressing disease. In a typical case there are four of these symptoms: (1) Intermittent clonus, (2) localized sweating, (3) polyuria, and (4) testicular pain. Their coexistence and number alone justify the hypothesis of syringomyelia. The burning and smarting pains have no relation to the joint lesions except as they are coexistent. They have no differential diagnostic value between tabes and syringomyelia, but if their central origin is admitted there is no ground to doubt that they are also dependent on the spinal lesion.—*Archives Générales de Médecine*, No. 52, 1903.

The Action of Corrosive Sublimate on the Spinal Cord.—Dr. Aldo Tartarini-Gellerani thinks that if corrosive sublimate is injected into the cortical substance of the spinal cord of a rabbit we find a deposit of lime salts in the small vessels surrounding the seat of injection. The deposit of calcareous salts does not appear in the first days after the injection, which causes at first only some necroses in the various envelopes of the cord. The loss of substance consequent to the lesion is at first replaced by fibrin and cellular infiltration, afterward by the proliferation of connective tissue; and the space is filled by granulation tissue, which gradually becomes cicatrix. In the second period the calcification appears (ninth or tenth day) and it continues up to the fifteenth day after the injection. This remains circumscribed at the point of injection. There is no fatty degeneration. The calcification occupies in preference the epithelium of the tortuous blood-vessels, and is very like that described in poisoning by mercury introduced in other ways. The calcification may vary in quantity from a deposit of a few calcareous granules to the filling of the vessel by the crystals. The most extreme result is a complete occlusion of the vessel by a calcareous cylinder. The calcareous deposits were tested by their solubility with effervescence in dilute mineral acids, and the formation of crystalline sulphate of calcium with sulphnric acid.—*La Riforma Medica*, No. 51, 1903.

Organotherapy in Renal Insufficiency.—J. Renaut concludes that macerated kidney is the most effective remedy for renal insufficiency that has yet been suggested. Better than all known remedies, it clears the kidney of œdema, because of its rapid and intense diuretic action, and when it is given for a long time it restores and maintains the urinary excretion. It does all this without any prejudice to the diseased kidney, and also reduces the amount of albumin at the same time that it restores the function of the kidney. It may even remove the albumin for long periods, and thus allow the restoration of the renal epithelium in the cases not too far advanced. When taken by the mouth it exercises a true antitoxic action, because its antitoxin is not injured in its passage through the digestive tract. If taken in too great a quantity it may excite slight disturbances, as pruritus, urticaria, millium, attacks of sweating, and, after a fortnight, a little dyspepsia. It has never caused important complications, but has almost unexpectedly exercised its antitoxic action. High arterial tension and passive dilatation of the heart, have always grown less under its influence if its use was sufficiently prolonged. This treatment should be followed in all cases of nephritis from the beginning, at least in connection with the other remedies, especially when any intoxication is evident. The difficulty of the procedure is the inconvenience of preparing the macerated kidney in the proper way every day. It is difficult to impress the patient, his nurses, and others of the necessity of coöperation with the doctor to save the patient's life.—*Revue de Thérapeutique*, No. 1, 1904.

The Relation between Unilateral Aural Disease and Hallucinations of Hearing.—I. Capgras finds that these relations vary with the disposition of the patient and the effect of the lesion on the sensorial and intellectual elements of which all hallucinations are composed. There are five distinct categories. (1) A patient having a tendency to delirium but not to hallucinations allows only the delirious interpretation of the functional disturbance to take place. This condition is distinct from hallucination. (2) The unilateral lesion can exist with independent hallucinations. (3) The unilateral affection can work on the sensorial element alone without affecting the intellectual element. In this case despite the unilaterality of the lesion the hallucinations are bilateral, and they stop with the cause which originated them. (4) The unilateral affection has no effect on the sensorial element. It is not the provoking cause of the hallucinations; but through the intervention of the intellectual element it determines the unilaterality because it furnishes a point of departure. This condition disappears only after a cure of the lesion. The hallucinations have been known to become bilateral (one case). (5) The unilateral lesion has a double rôle when the two preceding categories are united. It acts at the same time on the sensorial and on the intellectual elements. The first action determines the apparition of the hallucinations, the second accounts for their unilaterality. The progress of the lesion and that of the hallucinations are therefore parallel and their cure simultaneous, which is the case in the majority of unilateral hallucinations.—*Archives de Neurologie*, December, 1903.

Annals of Surgery, November, 1903.

The Diagnosis and Treatment of Acute Pancreatitis.—George Woolsey gives details of three cases coming under his personal care. He includes in his consideration of the subject those cases of pancreatitis beginning suddenly and severely, usually but not always accompanied by pancreatic hemorrhage and often associated after a few hours with fat necrosis. He presents the following conclusions: (1) In the severe acute cases of pancreatitis, the symptom complex, in connection with some predisposing factor or factors, and perhaps some other early signs, renders it possible to make a probable diagnosis. (2) The diagnosis is easier than in the less acute cases. (3) It is only likely to be mistaken for conditions which also require early operation. (4) The finding of fat necrosis at the operation confirms the diagnosis. (5) The treatment should consist of early operation, including infusion for collapse, evacuation, and drainage. This may be done under local anæsthesia. (6) Extensive or prolonged operations are not justifiable.

Recurrent Dislocation of the Ulnar Nerve Cured by Operation.—Farrar Cobb has found fifteen cases of dislocation of the ulnar nerve recorded in surgical literature. The accident may happen from "habitual" or idiopathic causes or from trauma. His own patient was a man aged fifty-two years who struck his elbow while trying to save himself from a fall. The diagnosis was not difficult. Operation revealed that the arcuate ligament passing over the nerve had been torn by the accident and that the long groove normally occupied by the nerve had become filled with muscular fibers. The groove was cleared out and an artificial restraining ligament constructed from the surrounding fascia. Two and a half years later the motion of the arm was in every way normal. Cobb declares that one must conclude that operation for this condition has every chance of perfecting a cure. It should be remembered that only the severe cases, few in number, and for the most part traumatic, need ever to be operated upon. Operation should never be undertaken for dislocation of the nerve alone, but only for the symptoms caused by the recurring dislocation, and only in those cases in which the symptoms are severe and disabling. The steps of the operation are simple, and will necessarily be the same in the majority of cases.

The Surgical Problem in Prostatic Hypertrophy.—G. W. Hawley offers as his conclusions from a study of this problem, the following: (1) That it is not the prostate but the adjacent urinary tract which demands relief. (2) That the direct cause of the interference with urinary evacuation is the displacement of the outlet and floor of the bladder resulting from enlargement of the retrourethral portion of the prostate. (3) That until the precise cause of prostatic overgrowth is known and successful preventive measures evolved, we can only hope to relieve this condition by correcting the displacement. (4) That until an effectual method which is sufficiently safe and simple for application before infection and disorganization of the urinary tract has resulted, surgery cannot bring any great relief. (5) That the logical mode of correcting vesico-urethral displacement is by reduction is evidenced by the fact that operative methods improve urinary evacuation

by virtue of their power to reduce, more or less successfully, this displacement. (6) That while some of these methods partially (sometimes completely) accomplish reduction with comparative safety, and others entirely reduce the displacement, but at considerable risk, none does so with both safety and success. (7) That since the reduction of the vesicourethral elevation is essentially a mechanic problem, reduction based on anatomic and mechanic principles should prove the simplest and safest method.

Splenectomy for Banti's Disease.—C. G. Levison relates a case of this nature, the operation being followed by thrombosis of the right internal jugular, subclavian, and innominate veins. Recovery ensued. The interesting features of the case as summarized by the author are the following: First, the long period of personal observation (eight years). Second, the invasion of the disease, preceded by an infectious appendicitis. Third, the intervals of perfect health, interrupted by profuse bleedings. Fourth, the blood findings, which corresponded in every particular to Senator's description. Fifth, the exacerbation of temperature and the accompanying leucocytosis, both indicative of some form of infection. Sixth, the slate-colored stools and the diarrhœa, evidence of a digestive disturbance. Seventh, the severe pains between the shoulder-blades, and the enormous quantities of morphine given necessary to relieve pain. Eighth, the disappearance of the distended abdominal and chest veins, followed by the spontaneous disappearance of the ascites. Ninth, the splenectomy, followed by the rapid increase in the percentage of hæmoglobin. Tenth, the appearance of the normoblasts and the megaloblasts in the blood subsequent to the splenectomy. Eleventh, the rapid regeneration of a very abnormal blood. Twelfth, the disappearance of the melanoderma following the operation. Thirteenth, the thrombosis of the right innominate, subclavian, and internal jugular veins, and the recovery of the patient from the same.

One Thousand Abdominal Closures by a New Method without a Known Hernia.—The paper of J. F. Baldwin is a plea for the use of annealed iron wire, tinned. It is strong, tough, flexible, and cheap. It is obtained in the hardware stores. The steps of his method of closing the abdomen may be thus summarized. The bellies of the recti muscles are exposed so as to allow of exact apposition from the tightening of the sutures. Through-and-through silkworm gut is then introduced *from within out*, catching the peritoneal edge, and then passed well back through the muscle and fascia and out at a proper distance from the skin margin. The fasciæ are now brought together in an over-and-over stitch by a double coarse thread of silk or cotton. This is so used as to allow of the wire being hooked into a long loop over which is hooked the wire. A handled needle with an eye at the point is then introduced through the skin and fat about an inch from the other end of the incision, and brought out just above the fascia so as to engage the other end of the wire, which is then withdrawn. This needle has been previously passed through two pads, about an inch square and made of six or eight thicknesses of gauze. Before withdrawing the wire from the needle, one of these gauze pads is slipped down over the wire so as to rest next to the skin. The other end of the wire is then threaded through the needle and the other gauze pad placed in position, and a perforated shot placed outside of each pad. The incision is then carefully dried, if there has been any oozing, and while an assistant draws up the ends of the silkworm gut, so as to secure apposition of the peritoneum throughout, the wire helix is drawn straight by traction with forceps on each end, care being taken to see that no kinks are formed during this process. The wire should be drawn back and forth once or twice so as to be sure there are no kinks. The shot are now pressed down against the pads and clamped. The fasciæ are thus brought into absolute contact, no fat or muscle being included. The silkworm gut is then tied in the usual way, care being taken that it is not too tight. All dead spaces are thus obviated, and each tissue is opposed, layer to layer.

Annals of Surgery, December, 1903.

Local Anæsthesia.—F. G. Connell describes the various methods in use. The advantages are: (1) Removal of the danger of death on the table. Others which may be mentioned are: (2) Avoidance of the after-effects of general anæsthesia on the heart, liver, kidney, and lung; but postoperative pneumonia seems to occur about as frequently after one anæsthesia as the other. (3) No period of postoperative nausea, vomiting, or unconsciousness. (4) No danger of patient being drowned in fecal vomitus. (5) Patient being conscious, is able to assist the operator in various ways. (6) Reducing by one the number of assistants; although it will be found to be convenient to have an assistant at the head of the patient to encourage and reassure him, and to be ready to administer a whiff or two of chloroform, if necessary.

Method of Suturing the Prolapsed Kidney.—A. H. Goelet describes his method tested by 171 consecutive nephropexies on 134 patients. In thirty-seven both kidneys were fixed at the same time. There were no deaths and no failures to secure sufficient fixation. The method differs from the Brödel suture in the following particulars: (1) The apex of the triangle formed by the suture is above, the ends emerging on the surface of the kidney near together. In Goelet's suture the apex of the triangle is below, the ends of the suture emerging on the surface more apart from each other, because they are brought out and tied on the external surface. (2) The sutures are placed at a greater distance apart, the lower suture at the lower pole; and they include less area of surface. The author's suture does not include the lower pole, which is left normally free, and it includes a larger area of surface. (3) The suture material is silk, while his is silkworm gut. (4) The sutures are tied to and buried in the muscles, while his are brought out upon the surface and tied over a pad of gauze.

An Experimental Research into the Temperature Relationship Existing in Shock.—From an elaborate series of experiments on dogs, G. C. Kinnaman declares that shock must not be considered as due to the lowering or exhaustion of one bodily function, but as a composite condition embracing an interference with the normal height of the blood-pressure (lowering), an interference (lowering) with the respiratory act, and a marked fall in the body temperature. Of these, as shock increases in severity, the most uniform and progressive factor is the fall in temperature. That there is a relationship existing between the fall in body temperature and shock is evident by considering: (1) That in one series the fall in temperature *was* the *sole* cause of shock; (2) That where, by continuous bath, the temperature fell but one degree Centigrade (average), the respirations were increased instead of diminished, and the fall in blood-pressure was greatly lessened; (3) That by raising the body temperature previously lowered in shock, the respiratory rate was increased and the blood-pressure raised. This relationship may be thus expressed: (*a*) A sufficient fall in the body temperature *can* cause a decrease in the respiratory rate and a marked fall in the blood-pressure, which, together with itself, we designate as shock; (*b*) Conversely, a limiting of the fall limits the fall in pressure and prevents a fall in the respiratory rate. Therefore shock is limited or prevented. (*c*) Antagonistically, a rise of the temperature causes a rise in the blood-pressure and the respiratory rate (reduced in shock), with the result of a gradual amelioration of all the symptoms. Thus, of the three factors concerned, the temperature commands first place by its power of production, by its power of limitation, and by its power of amelioration of the composite condition—shock.

Traumatic Epilepsy.—J. C. McCoy refers to the great difficulty and almost impossibility of removing all the cicatricial tissue which, following head injuries, may cause sufficient brain irritation to set up epileptic seizures. Operation is justifiable, however, in all cases in which the seizures are referable to a recent trauma. He relates the case of a boy who was struck on the head by a piece of concrete falling from a building. Immediately after the injury he was taken to the hospital in a semi-conscious condition. A compound fracture of the skull was found over the frontal and parietal bones on the right side, and there was a fracture running back into the occipital bone. Still a third fracture extended down into the temporal fossa. The brain tissue was more or less lacerated. On the third day after the operation there was a convulsion on the left side. Attacks of this nature recurred at intervals for several months, and finally the area which had been involved in the fractures was again exposed, and found covered with cicatricial tissue. This was adherent to the edges of the bone, extended for a distance of two centimeters beyond the edges of the bone on the upper surface of the skull. It was closely adherent and incorporated with cortex over the entire area, and completely filled the cup-like depression in the anterior portion of the wound. This mass of cicatricial tissue was excised, the plug of tissue in the depression carefully removed, and the tissue dissected from the edges of the bone. A celluloid plate was inserted, but the seizures continued to recur, though less frequently than before. The area was opened a third time and a fresh plate was inserted. The subsequent history of the case is given, showing that the cicatricial tissue tended to recur, and that seizures were occurring from time to time.

Book Reviews.

DIE FUNKTIONSPRÜFUNG DES AUGES UND IHRE VERWERTUNG FÜR DIE ALLGEMEINE DIAGNOSTIK. Für Ärzte und Studierende. Von Prof. Dr. O. SCHWARZ in Leipzic. Mit Ein und Achtzig Figuren im Text und Einer Tafel, Berlin: S. Karger, 1904.

THIS volume, which is one of 322 pages, is divided into three parts, of which the first part, occupying seventy-two pages, is devoted to a consideration of the principles of optics, the eye as an optical apparatus, and a few pages to a description of glasses for the correction of errors of refraction. The second part deals with the methods for the examination of the various functions of the eye, the visual acuity, light sense, accommodation, visual fields in health and disease, visual memory sense, the iris in health and disease, the motility of the eyes and the anomalies of motility, movements of the eyelids, simulation defects. This part takes up 230 pages. It is followed by a third part which treats of the diagnostic value of the findings on examination of the eye, considering the significance of departures from the normal in refraction, acuity of vision, fields of vision, movements of the irides, extrinsic muscles, eyelids, etc., a part occupying eight pages. There is a comprehensive index.

The work is carefully prepared and is exhaustive. It is admirably adapted to the needs of the ophthalmologist who wishes to know more of the subject treated than he can obtain from the standard text books.

NORMAL HISTOLOGY, A Manual for Students and Practitioners. By JOHN R. WATHEN, A.B., M.D., Professor of Surgery and Gynecology, formerly Professor of Histology, in the Kentucky School of Medicine; Surgeon to the Louisville City, the St. Anthony's, and the Kentucky School of Medicine Hospitals, Louisville, Ky. Philadelphia and New York: Lea Brothers & Co., 1903.

THE present volume (one of the Medical Epitome Series, edited by Dr. V. C. Pedersen) is a condensed treatise containing the essentials of histology. The subject is too extensive for many of the modern practitioners to take up in great detail. For the purpose of review or examination, this little compend is most convenient. Enough embryology has been included to make the context clear. There are one hundred and fourteen illustrations in the text. The book is concluded by a special chapter on histological technique.

MODERN METHODS IN THE SURGERY OF PARALYSIS, with Special Reference to Muscle-grafting, Tendon-transplantation, and Arthrodesis. By A. H. TUBBY, M.S. Lond., F.R.C.S. Eng., Surgeon to and Lecturer on Clinical and Orthopedic Surgery, and in Charge of the Orthopedic Department at Westminster Hospital; Senior Surgeon to the Evelina Hospital for Sick Children; Surgeon to the National Orthopædic Hospital; Consulting Surgeon to the Hospital for Hip Disease, Sevenoaks; Corresponding Member of the American Orthopædic Association; Chairman of Council of the Society for the Study of Disease in Children, etc.; and ROBERT JONES, F.R.C.S.E., Honorary Surgeon to the Royal Southern Hospital, Liverpool; Hon. Surgeon Liverpool Country Hospital for the Chronic Diseases of Children; Corresponding Member of the American Orthopedic Association, etc. Illustrated by ninety-three figures and fifty-eight cases. London: Macmillan & Co., Limited; New York: The Macmillan Company, 1903.

THE writer presents here his personal experiences in treating, by the most modern methods, the sequelæ of congenital and acquired types of paralysis. The older methods he merely touches upon. He believes that muscular-grafting, tendon-transplantation, and arthrodesis promise to bring about an entire revolution in this department of surgery. The book is profusely illustrated, adding greatly to the value of the text. The author discusses paralysis in its different phases and divides the context into three sections: Infantile Paralysis or Acute Anterior Poliomyelitis; Infantile Spastic Paralysis, or Cerebral Paralysis of Children; and Paralysis and Deformities Arising from Injuries and Diseases of Nerves, and Some Degenerations of the Spinal Cord.

INFECTIOUS DISEASES: Their Etiology, Diagnosis, and Treatment. By G. H. ROGER, Professor Extraordinary in the Faculty of Medicine of Paris; Member of the Biological Society, Physician to the Hospital of Porte D'Aubervilliers. Translated by M. S. GABRIEL, M.D. Illustrated with forty-three Engravings. New York and Philadelphia: Lea Brothers & Co., 1903.

As the translator says in the preface, "The effect of the present volume is to harmonize any seeming antagonism between experimental research and clinical observation, and to reduce the theories of infection and immunity to the basis of practical utility."

For this purpose but few are fitted, due to their experiences being either that of the clinician or the laboratory experimentalist. Professor Roger has been an active worker in both fields and the symmetry of the book has thus been preserved. The work does not take up the different diseases *seriatum*, but rather the principles underlying them, treating of the etiology of infections, their pathogenesis, the effects of association of different microbes and their clinical manifestations. Some specially interesting chapters are written on the influences of infections upon the various organs, their capacity for begetting systemic reaction and the theories of immunity and predisposition. The significance of sclerotic changes, such as follow acute and chronic infections, is admirably explained by the author and will afford interesting food for thought to all readers.

The philosophy of the book is generally sound and convincing in so far as we can go with our present knowledge. The subject of therapeutics, which occupies the last two hundred pages of the book, is also presented in a novel way and gives evidence of the vast clinical experience from which the deductions have been made.

The author has presented his ideas with clearness and in a most readable manner and should win a wide audience among the profession.

THE PRINCIPLES AND PRACTICE OF SURGERY. For Students and Practitioners. By GEORGE TULLY VAUGHAN, M.D. (Univ. of Va.). Philadelphia and London: J. B. Lippincott Co., 1903.

THE author's object to present the subject of general surgery in "a way best adapted for the uses of the student and general practitioner." The range of general surgery to-day is a very wide one. In draughting a book for students and general practitioners, only such parts of the subject should be considered as they have most use for. These are etiology, pathology, symptomatology, and diagnostics, with the indications for treatment. Such a book would do well merely to mention the operations by name, referring the reader to other textbooks on operative surgery for descriptions of the operative procedures. In the book before us the author attempts to cover both fields, and must of necessity, in the very limited space, be incomplete. The student should have facts stated clearly, concisely, tersely, but not incompletely. What is given by the author is good—but there is not enough of it.

BLOOD-PRESSURE IN SURGERY. An Experimental and Clinical Research. The Cartwright prize essay for 1903. By GEORGE W. CRILE, A.M., M.D., of Cleveland. Philadelphia and London: J. B. Lippincott Company, 1903.

THE author opens up the new field of experimental surgery; the future possibilities of which and its bearing upon surgical practice cannot be estimated. The author experimentally proves that shock is due to an exhaustion of the vasomotor center, with consequent fall of blood-pressure. Stimulation of a totally exhausted center (deepest shock) is impossible; and of a partially exhausted center (milder shock) increases the degree of exhaustion. Vasomotor stimulants, *e.g.* strychnine, are consequently contraindicated in shock. As the heart (according to the experimenter) has little to do with the maintenance of blood-pressure, cardiac stimulants, such as alcohol and digitalis, have little value. Saline infusion raises, but cannot maintain blood-pressure; hence is of little value in shock. Adrenalin and external pressure (by the author's pneumatic suit) were the only means the author found, by which blood-pressure could be sustained. By artificial respiration, rhythmical pressure upon the thorax over the heart, and the infusion of adrenalin, with a rubber pneumatic suit, a patient conventionally dead for nine minutes was partially resuscitated for thirty-two minutes.

These are, in the main, the author's conclusions. Experimentally we must accept them as facts. In practice one sees in conditions of mild or moderate shock good results from cardiac stimulants, such as camphor, and from subcutaneous and intravenous injection of saline solution. In fatal shock (absolute exhaustion of the vasomotor centers) nothing has heretofore availed; the physiologists have not yet taught us how to restore activity to cells that have been paralyzed. The measures recounted by the author have partially resuscitated animals and one human being from conventional death, but they have not restored permanent activity to the vital centers.¶

COMPEND OF DISEASES OF THE EAR, NOSE, AND THROAT. By JOHN JOHNSON KYLE, M.D., Lecturer on Otology, etc., Medical College of Indiana. Eighty-five illustrations. Philadelphia: P. Blakiston's Son & Co., 1903.

THIS manual is No. 19 in the series of Compends issued by the publishers. It is essentially a compilation from the various standard works on these special topics. The illustrations are unusually good for a book of its class, and it will be of service to the student desiring to review for examination or as an introduction to more comprehensive treatises.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 7, 1904.

ANDREW H. SMITH, M.D., PRESIDENT.

Report on the Library.—This report showed that the library contained 63,691 books and 36,000 pamphlets, and that in 1903 14,243 readers availed themselves of the privileges of the library. The card catalogue of authors and that of subjects had both been materially enlarged.

Guides to Prognosis in Epilepsy, with Remarks on the Curability of the Disease.—Dr. WILLIAM P. SPRATLING of the Craig Colony, Sonyea, N. Y., read a paper with this title. He said that epilepsy was cured in 5 to 10 per cent. of all cases, but it required, as a rule, a long-continued course of treatment, never less than two or three years, and this treatment must be carefully mapped out. The failure to secure better results generally was commonly attributable to the failure to treat the individual and along very comprehensive lines. The drug treatment of epilepsy alone, while valuable in many cases, and of some use in every case, often failed completely. Guides to the prognosis in epilepsy were always uncertain and unsatisfactory until the treatment had been in operation for a period of six months to a year or more.

The speaker embodied in the paper a report of thirty-four cases of epilepsy, which, in his opinion, had been cured at the Craig Colony. It was his unqualified belief that the methods of treatment at the Craig Colony were the best yet devised, and that the system of records were as complete as it was possible to make them. It was his custom to follow the cases for years, and they instantly recorded every seizure occurring in the colony, giving its type, duration, and severity. The degree of success attained was measured by their ability to apply well-rounded forms of treatment to a visual malady, which was often only a symptom complex. He was personally so sure that epilepsy was a curable disease that he was obliged to feel that those who took a different view had not had a sufficient opportunity for treating this disease on a large scale, along broad lines, and for a sufficient length of time.

Age at Onset.—The first point of interest in connection with the cases reported was the age at which the disease began. It should be remembered that epilepsy was essentially a disease of early life. In 20 of the cases it began before the fourth year; in 9 between the tenth and twentieth years; in 4 between the twentieth and fortieth years, and in one after the fortieth year. Of the cases reported, 23 had grand mal attacks, 7 grand mal and petit mal attacks; 3 petit mal only; one hysteroepileptic convulsions of great violence, with occasional grand mal attacks, apparently unaffected by the hysteria. In 1,325 cases studied at the colony, 4 were classed as psychic only, yet he did not regard even this form of epilepsy as incurable in some instances. Fits that were localized at the beginning and later on passed into a more general form of epilepsy were sometimes observed. Of all the forms of epilepsy, the Jacksonian type demanded the earliest treatment.

Duration of Treatment.—The length of time the epileptic was under treatment was often far too short to be of any lasting benefit. The shortest period in the series under consideration was twelve months; the longest period was five years and a half, and the average for the whole number was three years. Persistency in the treatment was always to be commended; the patients and the friends should always be impressed with the necessity for this. In some cases there would be no material improvement for a long period, perhaps as much as a year, and then there would be a sudden reduction in the number of seizures.

Duration before Treatment.—In the cases under discussion, thirteen had suffered from epilepsy from one to five years; ten from five to ten years; seven from ten to twenty years, while four had had it twenty years or more. These figures seemed to indicate that while the degree of chronicity should have some weight it could not be held that even marked chronicity should be regarded as a bar to a cure. While it was generally true that the more frequent the attacks and the greater their number in the aggregate the less favorable the prognosis, there were notable exceptions to this rule. On the other hand, infrequent attacks did not necessarily argue for a favorable termination, and, in his experience, many of these cases required a longer period of treatment than the more severe ones. Some cases showed occasional attacks that were apparently the expression of the acme of some morbid attack from which the patient must obtain relief or become insane; in other words, the epilepsy must exist or else an active insanity would develop. According to his experience, insanity was not unlikely to be the final termination.

The Aura.—A fraction over 50 per cent. of the cases presented an aura of some kind, and in all but three the aura was sensory. Five had an epigastric aura, while the others were disturbances of sensation in some other part of the body.

Sex.—Twenty-five of the thirty-four cases were males, and nine females, but it was a well-established fact that twenty males had the disease to sixteen females. He was prepared to believe that after about the twentieth year the proportion of cures was somewhat higher in males than in females, but that there was no difference between the two sexes before this time of life.

Mental Condition.—There were types of epilepsy which destroyed all the faculties of the mind in a very short time, while other types of epilepsy left the mind unimpaired even for a long period of years. An impaired mental condition was often attributable to the prolonged use of the bromides. In a study of 1364 cases he had been struck with the undoubted relationship between the mental state, the age of onset of the epilepsy, and the average duration of the disease. The younger the patient when the epilepsy developed, and the longer the period without proper treatment, the more unsatisfactory would the mental condition become.

Epilepsy a Curable Disease.—He firmly believed that epilepsy could be cured, and could be acquired again. In this respect it did not differ greatly from insanity. It was difficult to see how any inflexible rule regarding the duration of treatment could be fixed. Some epileptics could be cured in two or three years, and remain so; others could be cured only with the greatest difficulty in from three to five years, and then could be kept so only with the greatest difficulty. He wished to assert his unqualified belief in the curability of the disease; not only could it be cured, but not infrequently cases, apparently the most hopeless, could be cured, uplifted, stimulated, and encouraged sufficiently to make them contented and useful members of their communities.

Epilepsy an Organic Disease, and Rarely Curable.—Dr. M. ALLEN STARR said it was a most fortunate thing that these colonies for epileptics should have been established in this country, and particularly that this Craig Colony should have been established in this State through the efforts of Dr. Frederick Peterson and others. It was not only a fortunate thing for the unfortunate epileptics, but for the members of the medical profession, for these colonies were under most capital supervision, and hence very valuable information regarding this disease was gathered and presented to the profession. He was very glad to hear these statements of the reader of the paper regarding his hopeful attitude as to the treatment of the disease, and his statements with regard to individual cases. Evidently there was a certain amount of hope that could be held out to these patients. He thought it was undoubtedly only along the lines of constant observation and of control of

the life, habits, diet, and entire régime of the individual that one could hope to do a great deal for those suffering from epilepsy. Those who had had to deal with epileptics in dispensary practice knew how difficult it was to accomplish anything, a fact which probably explained to some extent the pessimistic view which the statistics from this source seemed to justify. On the other hand, in the treatment of epilepsy among the higher classes under excellent environment, he regretted to say that his experience did not lead him to subscribe to the statements that had been heard regarding the curability of epilepsy. He was free to admit that any one who had studied epilepsy extensively had seen occasional cases in which recovery had taken place, but these results were certainly exceptional. This subject had been recently discussed in the neurological societies of New York and Philadelphia, and while the members were willing to say that they had seen occasional instances of recovery, they had been compelled to admit that the vast majority of their epileptic patients did not get well. That had also been his own experience. In many cases, while one might reduce the number of the attacks, lengthen the interval, make the attacks themselves less severe and produce general improvement, yet, according to his experience, a cure of epilepsy was a very rare thing. Perhaps his dispensary records should be excluded, yet out of two hundred and fifty consecutive cases of epilepsy in private practice he could only recall one patient who had recovered, and had remained free from fits for a period of seven years. It was very rare for him to see a patient who could go more than a year or a year and a half without either a series of attacks or at least one or two. For these reasons he had come to take a rather pessimistic view of the results of treatment in epilepsy. Studying these cases he had also come to find a reason for this pessimism. He did not believe that epilepsy, except in a very small percentage of cases, was a functional nervous disease. He would admit that in a certain proportion of cases the fits might be of toxic origin, that they might arise from some disorder of metabolism of undetermined nature; but the vast majority of epileptics he believed were suffering from an organic nervous affection, the result of imperfect development of the brain. This would explain why epilepsy developed in early life. These patients presented stigmata of degeneration, which were not post-epileptic but prior to this disease, and they pointed to an imperfect development of the nervous system. Another argument in favor of the organic nature of epilepsy was found in the great resemblance between cases of Jacksonian epilepsy and cases of ordinary epilepsy. Jacksonian epilepsy was known to be due to organic disease in the brain; this was admitted by the majority of authorities. Jacksonian attacks of epilepsy were almost uniformly preceded by certain definite auras, and these auræ indicated the source of the irritation in the brain which resulted in the Jacksonian attack. The resemblance between the aura in Jacksonian attacks and in general epileptic seizures was very striking, and the fact that, in the majority of patients with epilepsy, the aura was uniform showed that the impulse always started from the same focus of irritation. His belief that epilepsy had an organic basis did not prevent him from treating this disease, but it did prevent him from taking a very hopeful view of the results of such treatment.

Optimism Concerning Epilepsy.—Dr. L. Pierce Clark said that the data on which the paper of the evening was founded had been accessible to him; indeed, some of it had been collated by himself. He agreed very heartily with the statements made by the author. He would place the rate of recovery at between 5 and 10 per cent. It should be remembered that a public place, such as the Craig Colony, did not usually receive a very hopeful class of patients, a fact which should be taken into consideration in the analysis of the results. His own private practice yielded fully 25 per cent. of cases of epilepsy in which the patients had gone two or three years without a seizure, although having them frequently before coming under his treatment. The aura was more elaborate and slower in its development in the more hopeful cases, a fact which he believed had an anatomical basis. It showed the unwillingness of the central nervous system to coöperate with a certain center which, as it were, was trying to establish an epileptic seizure. He believed with Dr. Starr that we were coming more and more to the view that epilepsy is an organic affection. Strangely enough, relatively few observers considered epilepsy as an organic affection, but he personally believed that there were definite demonstrable microscopical changes in the cortex which were induced by certain toxic and autotoxic agents of which we had almost no knowledge at the present time. The bad prognosis was largely due to the fact that the disease was associated with destructive changes in the cortex of the brain; nevertheless, he could not see why these processes should not be arrested or materially modified by treatment. He was decidedly optimistic regarding the curability of epilepsy after excluding the particularly gross organic cases, such as the palsies. This conclusion had been reached after eight or ten years of almost constant observation and study of this disease.

Dr. Frederick Peterson said he believed the attitude of the profession with regard to the prognosis of epilepsy should be about as follows: There was scarcely any cases, he thought, in which there was not a possibility of improvement. In all cases, good and bad, 6 per cent. at least could be cured. The organic cases were the most difficult of treatment, those cases due to injuries of the brain in infancy, occurring in connection with hemiplegia, and those occurring later in life from thrombosis, etc. The epilepsies coming on later in life were probably the most promising. If one could select a number of apparently the most favorable cases, about 20 per cent. of them could be cured. This statement seemed to be justified by the experience at Bielefeld, and at the Craig Colony, and the experience of well-known writers on this subject. This was the position which the physician should feel justified in assuming—indeed, was almost bound to assume, when explaining the situation to the patient or his relatives. It was impossible to fix any definite period of time which should be considered evidence of a cure. Formerly, two years was considered a sufficient time. His own belief was that a case could be called cured when this habit of explosion had been corrected and held in abeyance for years. This habit was something like the drink habit. We should look upon the cures of both classes of cases in the same light. The number of cures reported from the Craig Colony was small as compared with the number of patients admitted and cared for there, but it should be remembered that the cases received at that colony had so far been the accumulations of the almshouses for years and years. Probably fifteen or twenty years hence, when these bad cases were dead and the colony had come to be so well known that the cases would be admitted in the early stages of the disease, the percentage of cures would increase.

Dr. Ralph L. Parsons said that many years ago a large number of epileptics were under his care in the New York City Asylum for Insane, and in the Hospital for Epileptics and Paralytics. The character of the cases under his care at that time was such that one would be justified in holding the most pessimistic opinion regarding the cure of epilepsy; nevertheless the treatment did ameliorate their condition sufficiently to justify the hope that under better conditions the results would be more promising. He could not recall that a single one of the patients under his charge at that time recovered, and it could not be expected that they would do so. A few cases since that time had recovered under his care. One of these had gone thirty-five years without having had an epileptic seizure. According to his observations, epileptic convulsions taking place in the presence of other epileptics were

prejudicial to these other persons; hence he thought it was not possible to get the very best results in large public institutions.

Dr. JOSEPH COLLINS said it was most encouraging to learn that there was at least one asylum superintendent who knew something more than the superintendence of buildings, the laying out of gardens, and could do a certain amount of clerical work. The paper of the evening had contributed important facts to the science of medicine. He was disposed to believe that it was not at all extravagant to state that 10 per cent. of epileptics could be cured. He would like to go on record as subscribing verbatim to the statements made in the paper, with one exception, *i.e.* that the prognosis was better in epilepsy developing late in life, for, according to his experience, this form of epilepsy was due to arteriosclerosis and was commonly followed by general paresis. He maintained that epilepsy might, or might not, be an organic disease; the one who held that it was of organic origin was as much entitled to his opinion as was he who maintained that it was purely a functional disorder. He had it directly from the mouth of Jacksonian himself that the form known as Jacksonian epilepsy was not an organic disease. The speaker said he could not agree to the statement that had been made, that patients presenting stigmata of degeneration justified a worse prognosis; indeed, his opinion was just the opposite of this. He had no patience with those who insisted upon some definite period of immunity from seizures as a guarantee that a cure had been effected. In conclusion, he would say that he was not familiar with any nervous disease of similar severity which was entitled to a better prognosis from intelligent, assiduous, and proper treatment than was this disease, epilepsy.

Popular Prejudice against Colonies.—Dr. W. M. LESZYNSKY said that nothing had been said about the lack of willingness of many epileptics to sacrifice their personal liberty with the object of going to the Craig Colony, even though this was the very best thing for them. He had found in dispensary practice that even though it were possible to gain admission for patients to this colony, the majority of this class of persons were entirely unwilling to go there. They could not be blamed for this attitude, particularly where they only had three or four attacks a year and were able to continue at their work.

Organic and Incurable Not Synonymous.—Dr. B. SACHS said that epilepsy was almost as severe a scourge as was tuberculosis, because it not only affected a large number, but the affected persons commonly lived many years and became a heavy charge upon the community. It was a common experience to find that the parents of epileptics often showed evidence of having neglected their children because of the belief that epilepsy was incurable. This was one reason for taking a more optimistic view. For many years he had taken such a view himself, and had endeavored to exercise his personal influence toward spreading this gospel among the people. He could recall patients who had remained free from epileptic seizures for fifteen years; others who had been free from them for three, four, seven, and ten years. If a patient remained free from epileptic attacks for two or three years he should feel hopeful of a permanent cure, and should feel quite certain of it if the period was as long as seven years. He was sorry that nothing had been said in the paper regarding the treatment of these thirty-four cases which had resulted so satisfactorily. He was disposed to take the middle ground regarding the nature of epilepsy. Some years ago he had pointed out that a larges number of cases of epilepsy were due to distinctly organic causes, and that many cases usually considered to be ordinary epilepsies, were really associated with the early palsies. However, there still remained a very large number of cases which must be considered functional simply because we were ignorant of the underlying morbid condition. Some of the organic changes which had been detected might be secondary and not primary. Even if there were slight changes in the cortical cells, it did not follow that epilepsy was incurable, because he could not bring himself to make organic and incurable synonymous terms. There was one principle of treatment which was of the greatest importance, and that was individualization. Great pains should be taken to ascertain and remove the exciting cause. This exciting cause might be an intestinal intoxication or something else. Above all things, for the sake of the community, we should drop the notion that epilepsy is an incurable disease; he believed it to be curable, and the more so the more we endeavored to analyze this disease and treat it in accordance with the results of such analysis.

Dr. STRATLING closed the discussion. He said that he had not attempted to set any limit of time as indicative of a cure—certainly not seven years—but he had mentioned incidentally that one of the patients had now gone seven years without any seizure. More than 50 per per cent. of the cases received at the Craig Colony he had regarded as absolutely incurable at the time of their admission. This would leave six or seven hundred, of which number thirty-four were cured. It should be borne in mind that all of the cases were chronic ones. With regard to treatment, he would say that the day had gone by when one could say, "this patient has epilepsy; we must give him bromides." He had found it difficult to properly control the patient and systematize the treatment among the well-to-do, except when the patient had been removed from home. If the State of New York would undertake to give the Craig Colony a proper equipment, proper apparatus, drugs and especially competent physicians with sufficient remuneration to make them stay there, he would guarantee that the proportion of cures of epilepsy would be not less than 25 per cent. The State paid large sums of money for charity, and could afford only a small sum for the Craig Colony—at present, only $2.80 per week for each patient. The subject of prognosis was so broad that he did not feel that there was time this evening to take up also the question of treatment.

Stated Meeting, Held January 21, 1904.

ANDREW H. SMITH, M.D., PRESIDENT.

The Behavior of the Costal Arch in Diseases of the Abdominal Organs, and Its Importance as a Diagnostic Symptom.—Dr. ELLSWORTH ELIOT, Jr., presented a paper with this title. He said that in a normal state the costal arch participated in the respiratory movements of the chest and abdomen. The arc of excursion gradually diminished as the person grew older. In the healthy adult the completion of ossification in the contiguous ribs accounted for the fact that the movement of the costal arch was not so extensive as in children, although it was very much more extensive than in old persons. Asymmetry of the elastic recoil of the costal arch was observed chiefly in connection with contiguous neoplasms and cysts, and in inflammatory conditions after the subsidence of the acute stages. Any change in the passive movement of the arch could be detected naturally only by palpation, and in eliciting this sign not only should the resistance to the finger be determined, but also whether the resistance was participated in equally by the entire arch or chiefly by one of its segments. The examination should always be conducted with the patient in the dorsal position, and the abdominal muscles should be relaxed by flexion of the thighs, and having the patient breathe quietly with the mouth open. The extremities of the second, third, and fourth fingers of the hand should be placed upon the corresponding segments of the costal arch, and quick pressure should be made during expiration toward the vertebral column. Proceeding downward and backward from the sternum to the tenth rib, successive segments should be compared with one another. In case of bilateral costal resistance, pressure exerted simultaneously on the costal arches would decrease the distance between them to a very

much less extent than normal. The greater normal elasticity of the sternal extremity must not be forgotten, and also the desirability of comparing the abnormal with the normal side. Under normal conditions, the costal arch might be compressed in this manner a very appreciable distance. In children this distance was somewhat more than an inch, while in adults it varied between half and three-quarters of an inch, and in old people was considerably less than half an inch. In the presence of an acute or subacute inflammatory process the costal resistance was highly elastic, and its movement was quite limited. Asymmetry of costal resistance might be detected when there was no marked difference in the respiratory movement of the costal arches. Increase in costal resistance might, or might not, be associated with tenderness on pressure. The behavior of the costal arch in the presence of painful inflammatory conditions of the lower half of the abdominal cavity sometimes deviated from the normal. In these cases the respiration was largely thoracic, and there was a symmetrical decrease in the costal respiratory movement.

Dr. Eliot then demonstrated the method of examining the costal arch, and reported a number of operative cases to show the accuracy of this diagnostic sign in various pathological conditions in the abdomen. The speaker said that rigidity of the costal arch was present in a very large number of cases of abscess and inflammation of the gall-bladder. In neoplasm the symptom was of value only when the liver was increased in size. The sign was often of value in differentiating between acute appendicitis and cholecystitis. The presence of costal resistance almost always excluded appendicitis. In subacute cholecystitis a considerable degree of costal resistance was present. Only one opportunity had been afforded for observing the behavior of the costal arch in acute pancreatitis, but in this case the increase in resistance of this arch was very marked. In cases of pancreatic cyst the symptom occurred only when the cyst was so situated, or had reached such dimensions as to lie under the second costal arch. When the kidney was increased in size, or there was a paranephritic abscess, the symptom was of value. In all cases of enlargement of the kidney, whether inflammatory or neoplastic, the increase of resistance was invariably most pronounced in the lower segment of the arch. In several cases of calculi in the kidney no increase in the resistance of the costal arch had been noted. The following were some of the author's conclusions: (1) The symptom of costal resistance could always be elicited in an acute or subacute inflammatory process of the contiguous underlying organs. (2) In chronic inflammation of these organs it was present irregularly. (3) In neoplasms and cysts, increase of costal resistance could only be obtained when the tumor had reached a sufficient size to interfere mechanically with the motion of the arch. (4) The degree of resistance was in direct ratio to the intensity of the inflammatory process. (5) It was most marked in that segment of the costal arch most closely situated to the original point of infection, or, in the case of neoplasm, to that part of the arch which lay over the most prominent part of the tumor. (6) As a diagnostic symptom it was of the greatest value in pathological conditions of the upper half of the abdominal cavity. (7) The presence of asymmetry in the elastic recoil was very much less frequently observed than asymmetrical increase of costal resistance, the former being present only in cases of cysts, neoplasms, and inflammatory exudates in which the acute symptoms had subsided. (8) With the subsidence of the inflammatory process, whether by radical or palliative procedure, the costal resistance returned to its normal condition. (9) The presence of this symptom was very valuable, not only in facilitating accurate diagnosis, but also as a useful guide to that incision through which the inflammatory focus could be most rapidly exposed and satisfactorily treated.

Dr. Robert F. Weir said that the method proposed in this paper was not new, and had probably been more or less employed by most surgeons, and yet he was free to confess that he had not personally attached much importance hitherto to this mode of examination. The author had done a service in so carefully observing this diagnostic sign and presenting it in this interesting and accurate way to the profession. The value of the method had been abundantly demonstrated by the series of cases reported. It was true that many of those cases were associated with symptoms which general surgeons were accustomed to rely upon a good deal, such as rigidity of the abdominal muscles and the presence of certain characteristic points of pain. However, in a few of the cases reported these well-known signs were absent, and, hence, the great importance of the costal arch sign. The test was so easily applied that the general practitioner as well as the surgeon must feel indebted to Dr. Eliot.

Dr. A. Jacobi regretted that the reader of the paper had not stated the condition of the costal arch after recovery. It occurred to him that a number of conditions might impair the value of this diagnostic sign. For example, there were changes in the chest wall of long standing which might easily greatly modify the behavior of the costal arch. The rachitic rosary would be perceptible not only in childhood, but throughout later life. In these rachitic subjects the ribs would be found thicker, harder, and more resistant than normal. It had long ago been claimed that premature ossification of the upper ribs predisposed to tuberculosis; if such premature ossification took place in the lower ribs this would certainly modify the behavior of the costal arch and interfere with the diagnostic value of the sign under discussion. In tall men with long chests one frequently met with a certain amount of ptosis of the liver and spleen. With this was associated a certain degree of ptosis of the heart, a condition recently described by Dr. E. G. Janeway. It was conceivable that the immobility of the diaphragm associated with peritonitis might interfere with the proper interpretation of the behavior of the costal arch. In old cases of thickened pleura there must be abnormal rigidity of the costal arch. These facts suggested that the method might not always be easy of satisfactory application. In an ordinary ulcer of the stomach one would not expect any abnormal action of the costal arch; the reason the sign was of value in the case of perforating ulcer of the stomach reported in the paper was that this was associated with peritonitis.

Dr. A. Ernest Gallant said that he had noticed a rigidity of the costal arch in cases of jaundice and of hydronephrosis associated with movable kidney, but he had never before compared the two sides, and, hence, had not learned to appreciate the true value of this diagnostic method. There must be a considerable difference in the resistance of the chondral border in women and in men

Dr. Eliot closed the discussion. He said that his remarks were based upon the normal stage of the costal arch, and he had specifically stated in one or two instances that the arch had returned to its normal condition after recovery. He did not think the value of this diagnostic sign would be materially impaired by the pathological state of the costal arch resulting from rachitis; certainly it would not be if the rachitic changes were symmetrical.

To Distinguish Pseudolymphocytes from Lymphocytes.—According to H. C. Earl, the following points will assist in distinguishing pseudolymphocytes: (1) Neutrophile granules may be found in them; (2) their zone of protoplasm is generally wider than that of lymphocytes; (3) they are naturally more common in effusions of a polynuclear character; (4) when stained with methyl-green pyronin their protoplasm only takes on a light rose color, while that of lymphocytes stains a deep red.—The *Dublin Journal of Medical Science.*

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

(Continued from page 196.)

THIRD DAY—THURSDAY, JANUARY 28.

Old Time of Meeting Restored.—The action of the society, changing the time of the annual meeting to Tuesday noon and Thursday evening, inclusive, was reconsidered, and, after some discussion pro and con, it was finally voted to go back to the old order of things.

Officers Elected.—*President*, Dr. Hamilton D. Wey of Elmira; *Vice-President*, Dr. Joseph D. Bryant of New York; *Secretary*, Dr. Frederic C. Curtis of Albany; *Treasurer*, Dr. O. D. Ball of Albany.

A Case of Recurring Membranous Stomatitis Associated with Erythema Exudativum Multiforme (Hebra).—Dr. LOUIS E. BLAIR of Albany reported this case. A peculiar phase was the appearance of the skin affection at least one week after the mouth disease. It lasted for four weeks, but left coppery stains, which were visible for months. White, contracted scars could be seen a year later. There were several subsequent attacks. The membrane in the mouth was firmly adherent. The mucous membrane about the anus, glans penis, and urethra was covered with a membranous deposit. The eruption on the skin, when at its height, resembled a confluent variola.

The Hospital Car; Its Equipment, Use, and Importance.—Dr. W. W. SANFORD of New York read this paper. He described a modern hospital car. It was sixty feet long, finished in white within and without, and was practically dustproof. It was divided into two compartments, a small one for an accident ward, and a larger one for a hospital ward. Sliding doors were provided for the passage of stretcher carriages. The car was well lighted from above, both by day and by night. Experience, he said, had abundantly proved the value of these cars, and their more general adoption should be urged by the medical advisers of railroad companies.

Symposium on Nephritis.—The following papers were the only ones presented in this series:

Renal Decapsulation from the Pathologist's Point of View.—Dr. J. M. VANCOTT of Brooklyn sent a paper on this subject, which was read by his colleague, Dr. Murray. The author first described the renal circulation very minutely. He pointed out that three-fourths of the blood supply passed anteriorly, and that the supply was distinctly an end-artery system. From this consideration of the renal circulation it was concluded: (1) That the arteries were terminals having nowhere any direct communication with each other, the only possible communication being through the capillary system; (2) that all of the vessels varied systematically in diameter in certain locations, thus definitely affecting the blood-pressure in various parts of the organ; (3) that with the exception of a few of the interlobular arteries and a few arteries entering the cortex, the only communication was capillary. Therefore, by decapsulation the delicate parenchyma of the kidney was subjected to loss of nutrition and to alteration of pressure and reversal of the current in the vessels of widely varying diameter, conditions commonly found in connection with renal infarction. Litten's experiments had demonstrated that the collateral circulation was not sufficient to restore the equilibrium of the circulation in the kidney after decapsulation. The stripping of the capsule completely cut off what little peripheral circulation was derived from the capsular arteries. Summing up all the facts, the conclusion was reached that very little could be expected from the renal collateral circulation when the main supply of blood was compromised. It had been shown that regeneration of the parenchyma of the kidney did not occur, the repair always taking place in the usual way, *i.e.* by cicatrix. The author said that Dr. Edebohls's theory regarding renal decapsulation for the cure, or even the relief, of nephritis must fall to the ground. The fact seemed to have escaped notice that when the capsule was torn away the vessels that should renew the circulation were torn away also, so that nothing could be done in the way of restoring the circulation except by capillary anastomosis. It also seemed to be forgotten that there must be inevitably death of considerable areas of the cortical parenchyma, for the reason that all authorities agreed that renal epithelia die in two hours after being deprived of their blood supply, and it required at least four days for the production of new capillaries. The operation of Edebohls totally disregarded the fundamental principles held regarding chronic diffuse nephritis, for this disease was merely a local expression of a general condition. Where the kidney had been dislocated or pressed upon, it was easy to see how good might be accomplished by removing the abnormality, and so improving the circulation of the kidney. No amount of restoration of renal circulation could restore the integrity of the cortex. Drs. Vancott and Murray had made a series of laboratory experiments on cats, and, in general, they agreed with the experiments of Litten on the renal circulation. All of the new capsules showed a tendency to project new fibrous tissue into the cortex. Not the slightest evidence of regeneration of the cortex was found. These experiments showed that decapsulation worked only positive injury to the normal kidney, and was of no benefit to the large white kidney.

Surgical Treatment of Nephritis.—Dr. WILLIS G. MACDONALD of Albany made some remarks on this subject, in lieu of the paper on this topic that was to have been presented by Dr. Edebohls. Dr. Macdonald said that in those forms of nephritis dependent upon a general systemic condition, and associated with marked vascular changes and sterile or nontoxic urine, he did not believe any form of surgical intervention would be of avail. But in infectious nephritis, an inflammation of the kidney due to local bacterial infection by such germs as the gonococcus, streptococcus, and the staphylococcus, he expected aid from surgery. Again, in the so-called cases of surgical kidney in which there was suppression of urine within thirty-six hours after an operation on the genitourinary tract, ordinary medical treatment was usually powerless to avert the rapidly fatal termination. He had recently seen a case of this kind in which, after forty-eight hours' suppression of urine, incision of the capsule of the kidney resulted in a speedy relief of the urinary suppression.

General Treatment of Nephritis.—Dr. BEVERLEY ROBINSON of New York read this paper, referring only to acute and chronic diffuse nephritis. He said that a great many cases of acute nephritis were found to be grafted on a former process which had existed for some time, and had probably been caused, in the first instance, by harmful modes of life, or had developed in the course of some infectious disease. The first thing to do in all cases of acute nephritis was to put the patient to bed. He should be clothed in woolen and surrounded on all sides by blankets. Heat to the surface, continuous in character and more than agreeable, was imperatively demanded. The two cardinal principles to be kept in view were: (1) Physiological rest, so far as possible, to the diseased organ; (2) relief of function, especially through the supplementary action of skin and bowel. The first indication was supplied by going to bed, as already stated. The diet was next to be considered. During the great engorgement of the kidneys the food should be fluid, and given in small quantities, so as to least irritate the kidneys. The diet should be almost exclusively milk, and this should be insisted upon with certain sensible limitations. Milk did not agree with every person, however, when given undiluted and in the raw state. For many persons, one must use gruels, jellies, and, after a few days, amylaceous food. After a day or two, spring water should be given freely. To the water might be added a little weak tea. If the œdema or dyspnœa were threatening, or if the urine were scanty and concentrated, the bowel should be emptied rapidly

by enema and by salines. Then a hot wet pack should be given. Hot water baths were very troublesome, were no more efficacious, and were often dangerous if not given with extreme care. Hot-air baths were very useful in institution practice, but in private he greatly preferred the hot wet pack because of its simplicity. When there was pain over the loins, and especially if the urine were concentrated and contained much albumin and many casts, mustard poultices were useful by diminishing the congestion of the kidney. High rectal irrigations, by means of Kemp's tube, promoted diuresis. He was of the opinion that, in the adoption of this latter acquisition to our armamentarium, a means was at hand which, when suitably employed, was of the greatest value. Pilocarpin was a dangerous drug and should be avoided; he had known it to cause fatal bronchitis. If an attack of acute uræmia were impending, a few doses of nitroglycerin would often relieve the situation very rapidly. It was also well to add sweet spirits of nitre. This agent relaxed the arteries, acted as a diaphoretic, and was effective and innocent. It acted on the small vessels very much as did nitroglycerin and the nitrites. Abstraction of blood by wet-cupping or venesection was most valuable if the danger of uræmia were great, and it was often well to follow this by saline infusion. In a few instances it might be necessary to give chloroform by inhalation, or morphine hypodermically. He did not object so much to morphine in acute nephritis as in chronic nephritis, but he was still reluctant to give it except, perhaps, in convulsions of puerperal nephritis. In some of these cases repeated inhalations of oxygen were valuable in averting uræmia and in promoting recovery when uræmia was already fully developed. As the acute stage passed off, the fever would disappear and the blood would disappear from the urine. At this time, eggs, fresh fruit, bread, a little fish, puddings, and green vegetables might be added to the diet, and the patient be permitted to sit up a little. For the pronounced anæmia some good form of iron should be given; the best, in his opinion, was the old tincture of the chloride of iron alone or in the form of Basham's mixture. When possible, these patients should be removed to a warmer climate, if living in a cold and changeable one. The albuminuria might exist for a long time and prove very obstinate under treatment. Our aim should be to promote the general health in every way possible, and we should not forget to keep the bowels free and the skin active. Undue physical effort and indiscretions in diet must be guarded against. If the acute nephritis passed into the chronic form, nausea and repeated vomiting might require very careful treatment. After other means had been exhausted, he had occasionally found that repeated small doses of Kirchwasser (a dry alcohol containing hydrocyanic acid) beneficial. The diarrhœa of Bright's disease was sometimes controlled very satisfactorily by prolonged irrigation of the bowel. When the skin becomes very tense, several punctures or incisions should be made, under aseptic precautions, and the parts bandaged. Occasionally it was desirable to insert a small capillary tube into the skin and connect it with a small rubber tube in order to secure continual drainage into a vessel. When there was marked dyspnœa from accumulation of fluid in the abdominal cavity or in the pleural cavities, paracentesis of these cavities might be required. Cream of tartar drink was often very useful, unless the stomach did not tolerate it well. Digitalis, strophanthus, and strychnine often proved very beneficial.

In persons past middle life, digitalis could rarely be given with good effect unless its action on the peripheral vessels was counteracted by the addition of nitroglycerin. In the treatment of the fever it was important to avoid the use of chlorate of potash or of sodium salicylate, because of their well-known irritative action on the kidneys. It was wise in every case to watch the quantity of albumin and the number and nature of casts passed in the urine from day to day, and regulate the diet accordingly. In the infectious diseases we should be guarded about the prognosis on the occurrence of albumin and casts in the urine until satisfied that the infectious process had left behind it a damaged kidney. In all cases of prolonged albuminuria following acute nephritis, one should carefully guard against imprudence of diet, exposure to cold, and fatigue. If chronic nephritis persisted, one should be especially solicitous about the development of all subacute forms of nephritis. It was frequently difficult, or impossible, to treat the original cause of the chronic nephritis. If syphilis, malaria, or suppurative processes were present, we should not ignore the indications proceeding therefrom, but should remember that the medicinal treatment of these diseases sometimes caused increased irritation of the kidneys. It was a temptation to endeavor to combat an intestinal toxæmia, but in doing so we should be slow to make use of such drugs as the salicylates and phenol derivatives. In the chronic cases, too close confinement would result in diminished appetite and strength; hence, theory must be tempered by wisdom and practical experience. Among the remedies that had been vaunted for increasing the quantity of urine in chronic nephritis without increasing the albumin, must be mentioned iodide of potassium. Its use in large doses had been urged by Ringer, but the speaker said that he was not personally disposed to employ such large doses. Even in moderate ones, iodide was apt to derange the stomach and diminish the appetite. If headache, malaise, and disordered digestion were occasioned by a liberal diet, it should be abridged considerably, but if these did not occur, and the patient's general health and strength seemed satisfactory, he would persist in a fairly liberal diet, even though a considerable quantity of albumin was excreted. In general, sufferers from nephritis were better off without alcohol in any form, but there were exceptions even to this rule, he would not withhold alcohol if the person had been in the habit of taking it in moderate quantities for many years. It should be taken with the meals in small quantities, well diluted. When there was much exhaustion, small quantities of alcohol should be given for a time as both a food and a stimulant. There was much good authority in favor of the use of morphine in uræmia, but, personally, he had found it useful when the pupil was dilated, and harmful when the pupil was small. For sleeplessness he preferred the bromides to chloral. He had found saline irrigations of the bowel frequently as useful as intravenous injections of saline solution. In some of his worst cases of weak heart and general anascara he had obtained excellent results from Trousseau's Diuretic Wine, which is composed of digitalis, squills, juniper berries, acetate of potash and white wine. Certain experiments pointed to the value of theobromin as a diuretic.

Dr. Delancey Rochester of Buffalo said that he had yet to see the case of acute nephritis, with blood casts, and suppression of urine that had not been relieved by proper and energetic medical treatment. The vigorous use of cups, both wet and dry, together with leeching over the loin, and venesection were all indicated. When there had been suppression of urine for twenty-four hours, such measures would often cause a restoration of the excretion of urine. He believed the results from such medical treatment were just as good as from any form of surgical treatment.

He had been deeply interested in Dr. Robinson's presentation of the subject, but could not agree with him in confining the use of the hot-air bath to hospitals. With an "elbow" of a stove-pipe, an alcohol lamp, and a couple of barrel-hoops one could easily apply the hot-air bath in any private house in a most effective manner. For those persons who did not swea

readily, he would recommend the hypodermic injection of minute doses of pilocarpin, followed immediately by the hot-air bath. Where convulsions were present, he favored the use of a moderate dose of morphine, immediately followed by the hot-air bath. In following the course of a case of nephritis, it was fully as important to determine the total excretory power of the kidney, as indicated by the total quantity of urea and of urinary solids, as it was to note the presence of albumin and casts. The degree of anæmia present, and its character, as determined by an examination of the blood, constituted an important factor in the prognosis. When there was much œdema, it was not advisable to inject salt solution subcutaneously, but if the œdema were not marked the results were as good as from the intravenous injection of this solution. In subacute nephritis, good results were obtained by washing out the bowel carefully once or twice daily with saline solution, allowing a certain quantity to be retained. Experience had taught him that sometimes the presence of an excess of indican in the urine was the forerunner of an increase in the albuminuria, and that by prompt treatment it was possible in this way to avert attacks of uræmia.

Dr. S. B. WARD of Albany deprecated the common custom of physicians of telling their patients that they had Bright's disease simply because albumin and casts were found in the urine, for the laity were so terrified by this term that it was hard to counteract the first false impression. In cases of chronic nephritis he had found arsenic a valuable adjuvant to iron in the treatment of the associated anæmia.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LESSONS ON MASSAGE. By MARGARET D. PALMER Masseuse and Manager of the Massage Department of the London Hospital. 8mo, 261 pages. Illustrated. William Wood & Company. Price, $2.50 net.

TEXTBOOK OF LEGAL MEDICINE AND TOXICOLOGY. VOL. II. By FREDERICK PETERSON, M.D., and WALTER S. HAINES, M.D. 8mo, 825 pages. Illustrated. W. B. Saunders & Company. Price, cloth, $5.00; sheep or half morocco, $6.00 net.

THE TREATMENT OF FRACTURES. By CHAS. L. SCUDDER, M.D. Fourth edition. 8mo, 534 pages. Illustrated. W. B. Saunders & Co. Price, buckram, $5.00 net; sheep or half morocco, $6.00.

A MANUAL OF OPERATIVE SURGERY. By SIR FREDERICK TREVES, F.R.C.S. 8mo, 824 pages. Lea Bros. & Company. Price, $6.50 net.

NINETEENTH REPORT OF THE STATE BOARD OF HEALTH OF WISCONSIN, September 30, 1902. 8vo, 304 pages. Muslin.

THE PATHOGENIC MICROBES. By Dr. P. JOUSSET. 16mo, 192 pages. Muslin. Boericke & Tafel, Philadelphia. Price, $1.

THE BLUES (Splanchnic Neurasthenia): CAUSES AND CURE. By Dr. ALBERT ABRAMS. 8vo, 240 pages. Illustrated. Muslin. E. B. Treat & Company, New York. Price, $1.50.

ASTHMA IN RELATION TO THE NOSE. By ALEXANDER FRANCIS, M.B. 8vo, 136 pages. Muslin. Adlard & Son, London. Price, 5 shillings.

BACTERIOLOGY OF MILK. By Mr. HAROLD SWITHINBANK and Dr. GEORGE NEWMAN. 8vo, 605 pages. Illustrated. Muslin. E. P. Dutton & Company, New York. Price, $8.00.

THE PREVENTION OF CONSUMPTION. By Dr. ALFRED HILLIER. 12mo, 226 pages. Illustrated. Muslin. Longmans, Green & Co., New York.

FATIGUE. By A. Mosso. 12mo, 334 pages. Illustrated. Muslin. G. P. Putnam's Sons, New York. Price, $1.50.

Therapeutic Hints.

Clay Paste in the Treatment of Inflammations of the Skin.—Wet clay, in addition to other therapeutic actions, has the mechanical property of holding water and assisting osmosis. Those containing a large percentage of kaolin are preferred. The dressing should be kept constantly moist, which can be accomplished by covering the application with a wet towel a number of times a day. A good formula for the paste is as follows:

℞ Kaolin ..... 50 parts
Water ..... 25 parts
Petrolatum ..... 25 parts
Ichthyol ..... 4 parts

This will generally remain moist for forty-eight hours. In eczema rubrum this combination sometimes fails, when it is necessary to increase the quantity of kaolin and diminish the amount of petrolatum. Other substances may be incorporated with the paste to meet various different indications.—J. F. WALLIS in the *Therapeutic Gazette*.

To Check the Diarrhœa in Typhoid Fever.—

℞ Acidi carbolic .....
Ext. opii ..... āā gr. i
Bismuthi subnit ..... gr. xviii
M. et ft. pil. No. vi. S. 1 pill t. i. d.
—*The Medical Times and Hospital Gazette.*

Pain of Stomach Cancer.—This is due to the acids formed by gastric fermentation, the best treatment for which is a strong saturation powder:

℞ Lactose 1.0
Calcined magnesia 1.50
Bismuth subnitrate .....
Prepared chalk ..... āā .. 0.70
Codeine 0.01
Sodium bicarbonate 1.0

The lactose is to prevent the powder from caking. The codeine has a special sedative influence on the solar plexus. A. ROBIN.

Hemorrhage of Gastric Cancer as Shown by Black or Bloody Shreds.—

℞ Tannic acid 0.25–0.50
Opium 0.02
Calcined magnesia 0.10
—ALBERT ROBIN.

Malaria.—

℞ Tinct. iodi .....
Potassii iodidi ..... āā ℥i
Aquæ dest ..... ℥iii
M. Sig.: Tablespoonful at the beginning of the attack and repeated in twenty minutes if necessary.
—REGNAULT.

Neurasthenia.—

℞ Sodii glycerophosphatis ..... ℥ss
Calcii glycerophosphatis ..... ℥ii
Acidi phosphorici dil. ..... ℥vi
Aq. cinnamoni ..... q. s. ad ℥iv
M. et S.: Teaspoonful three times a day after meals.
—THOMPSON.

Flatulency is said to be relieved by one-grain doses of camphor given three times a day.

Agalactia.—

℞ Strychninæ sulphatis .....
Pilocarpinæ hydrochloratis ..... āā gr. i
Sacchari lactis ..... ℥iss.
Alcoholis ..... q.s.
Make 60 tablet triturates. Dose: One every four hours.
—*Philadelphia Medical Journal.*

Cardiac Hypertrophy.—

℞ Tinct. digitalis ..... ℥ii.
Tinct. belladonnæ ..... ℥i.
Tinct. cardamomi comp ..... ℥ii.
Elixir simplicis ..... ℥i.
M. et Sig.: A teaspoonful in water after meals.
—DA COSTA.

Angina Pectoris.—

℞ Sodii iodidi ..... gr. 80-160
Sodii arsenatis ..... gr. ¼
Aq. dest ..... q. s. ad. ℥v
M. Sig.: Two or three teaspoonfuls daily.
HUCHARD.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 30, 1904:

	Cases.	Deaths.
Measles	814	19
Diphtheria and croup	461	53
Scarlet fever	435	27
Smallpox	...	...
Varicella	156	...
Tuberculosis	316	149
Typhoid fever	24	7
Cerebrospinal meningitis	...	6

The Relation of Tuberculous Glands to Life Insurance.—The conclusions drawn by Daniel M. Eisendrath from a contribution to this subject are as follows: Tuberculous glands of the various regions are frequently followed by foci elsewhere, the lungs being most frequently involved (28 per cent.). Next in frequency are the bones and joints. Operative treatment is followed by the largest number of permanent recoveries (from 54 to 80 per cent.). Every insurance examiner should bear in mind the above figures and investigate carefully as to the possibility of a late infection following tuberculous adenitis in early life.—*The Medical Examiner and Practitioner.*

Cases Simulating Appendicitis.—H. A. Brennecke reports several cases of this nature which have come under his personal observation. One case was that of gangrenous pancreatitis. The patient was a man, forty-three years of age, strongly addicted to the use of whiskey. He was attacked with intense abdominal pain while drinking cold beer. On examination he was found to have diffuse pain and tenderness over the entire abdomen with obstinate constipation. An area of dulness extended from the region of the appendix toward that of the gall-bladder. The diagnosis was thought to lie between appendicitis and gall-bladder disease. A post-mortem examination revealed gangrenous pancreatitis. Another patient, a woman of forty-five years, weighing about 200 pounds, had a chill, severe pain in the abdomen, with symptoms of collapse. The temperature rose to 103°, and the pulse-rate varied between 140 and 150. The physicians consulted made a diagnosis of perforated appendix. The writer saw her a day or two later. The urine showed no sugar or albumin. There were about one or two tablespoonfuls of a whitish greasy substance floating on the bowel movements. Examination showed the bowel movement to be fat. The diagnosis of pancreatitis with general peritonitis was made. Unfortunately, a post-mortem examination was not allowed. The third patient was a young man of twenty-four years. He was taken with severe abdominal pains, chill and vomiting. The greatest tenderness was over McBurney's point. Hot packs and liquid diet were ordered, and the pain subsided. A little to the left of McBurney's point was a distinct mass about the size of a walnut. Operation was performed. The appendix was found normal, but immediately to the right of it was a mass. To the left were a number of enlarged glands. The mass contained cheesy pus. A number of macroscopical tubercles were seen on the peritoneal surface of the bowel. The pus was found to come from a caseating mesenteric gland. Other glands showed caseous areas. A number of ulcers were found on the mucous membrane of the bowel. The cause of death was probably a generalized miliary tuberculosis. A considerable number of cases of acute pancreatitis have been mistaken for fulminating appendicitis. The diagnosis of acute pancreatitis, in itself, according to the writer, offers great difficulties. In those cases seen by the writer, the most prominent symptoms have been sudden intense pain, tenderness over the entire abdomen, obstinate constipation, excessive tenderness over the epigastrium, and later icterus and fatty stools.—*Illinois Medical Journal.*

Ischæmic Paralysis.—Ischæmic paralysis was first described by Volkmann in 1875. The symptoms are paralysis and contracture of the forearm and fingers rapidly developing after injury, with an absence of pain. In several instances marked improvement has resulted from the application of operative measures, consisting of either simple division, or in the more elaborate lengthening of tendons by the Z-method. In either case passive movement is recommenced about a fortnight after the operation.—*Birmingham Medical Review.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended January 29, 1904:

SOME PERSONAL OBSERVATIONS AND EXPERIENCE OF THE SCHOTT TREATMENT OF HEART DISEASES.

By WILLIAM W BALDWIN.
ROME, ITALY.

THE Schott treatment of heart diseases was such a radical and startling innovation upon earlier methods that even now, after a generation's experience, it has not been as universally accepted or employed as its merits deserve. It has, however, grown in estimation, year by year, and although it may not have superseded classic remedies, at least it must be recognized as a most valuable addition to our means of relief and cure in this class of diseases. Indeed, while, perhaps it is still too early to draw comparisons between this and other modern medical discoveries, nevertheless, it must be confessed that "The Schott Method" is one of our great improvements in the healing art.

This method has the great merit of simplicity; it is not difficult to learn, and I think it might be employed successfully by every enlightened general practitioner; above all, its efficacy can be scientifically demonstrated. Where its indications have been determined, by expert diagnosis, the method has no drawbacks, if skilfully administered. Even personal idiosyncracy can be overcome by exercise of wise ingenuity. Its curative effects are not only greater, but generally far more permanent than those of the older treatment by means of drugs and rest. In a certain proportion of those cases when other treatment has hopelessly failed, this method often restores compensation, and sometimes it renders drugs unnecessary, or makes their assistance more successful. In grave cases, in which both treatments are necessary, the Schott method invariably increases the beneficial effect of the other, and makes it possible to give considerably smaller doses of drugs.

What physician cannot recall with regret his helplessness in presence of some case of growing failure of cardiac compensation and of the futility of classic remedies, when at last he is confronted by that ominous downward drift into the vicious circle, where the symptoms are more painful than the original disease, and the one pushes on the other through insomnia, breathlessness, ascites, pain, and those innumerable tortures which lead to the fatal ending. It is true that in some cases balance of vital resistance is so compromised that recovery is no longer possible, whatever the treatment employed. Indeed "life itself is a mortal disease." I believe, however, notwithstanding the limitations which nature herself has set to our art, that many cases of heart disease formerly considered hopeless can now not only be relieved of all the more distressing immediate symptoms, but that the life may be prolonged and rendered both useful and satisfactory.

That saline baths with a certain percentage of carbonic-acid gas, slow and strengthen the heart's action had long been noted, but no general therapeutic value was suggested in connection with this fact until the Schott brothers demonstrated that carefully regulated baths and resistance exercises, followed sometimes by regulated mountain climbing, invariably produced a marked improvement in the condition of patients suffering from various chronic heart diseases, and that in certain cases permanent cures were obtained. They proved that these methods, by stimulating a weakened heart to a greater activity, produced a tonic effect. In most cases of heart disease, either relative or absolute, muscular insufficiency renders it impossible wholly to overcome even the normal blood-pressure so as to complete the office of forcing its contents to the limits of the organism on the one hand, and to assist the return current by its mechanical suction on the other. Thus the invariable indication is to augment the working power of the heart, through increase of its muscular substance.

Cardiac muscular hypertrophy, which was formerly regarded as a dangerous symptom of disease, we now hold, with few exceptions, to be that curative compensatory process, to the accomplishment of which, we should direct our treatment. On the other hand, muscular heart weakness, so called cardiac insufficiency, leads to dilatation, through accumulated blood remaining in one or both chambers after an insufficient contraction. This is the direct cause of what we call disturbances of compensation.

The immediate indication in cases of this kind is to stimulate the heart muscle to stronger, more efficient systolic contractions, so that the heart may be able to clear its cavities of superfluous blood, for dilatation, whether caused by valvular disease or insufficient contractible power, always proves blood stasis in the heart itself. The heart contracts rapidly but insufficiently, so that after each short systole a mass of blood remains behind, the heart not having strength to overcome aortic pressure.

The Schott brothers demonstrated that both saline baths and resistance exercises stimulate the heart muscles to more powerful contraction, so that, although the aortic as well as the general arterial tension may be at first increased, the heart by and by wins so much power that it is able not only to vercome the same, but also completely to empty its cavities. The heart being thus cleared of residual blood, is also relieved in diastole of that intramural pressure which had nagged it to more rapid but inefficient contraction; above all, the lengthened diastole gives the weak and overworked organ a much needed interval for repose and recuperation.

The myocardium as well as the other tissues of the body receiving an augmented supply of richer blood, those reparative processes are inaugurated which must be the chief aim of our treatment. Were not this the case, a time would come when that reserve of nerve force, which we invoke to remove peripheral resistance on the one hand and to stimulate the heart to more powerful contractions on the other, would be exhausted; thus a cure would be obviously impossible.

The immediate effects of the baths are not so brilliant as those following the resistance exercises, but, on the other hand, at least in the beginning, they last considerably longer. We constantly observe lessened congestion in the short circuit, and often in the whole venous system; the respiration becomes slower and more efficient; the hepatic congestion diminishes, as can be proved by percussion; cyanosis diminishes, and cold extremities glow with warmth. During and after both bath and resistance exercises the pulse slows and grows stronger. In general, its resistance soon decreases, proportionately to the tonic vasodilation induced, although the impulse of more powerful, though slower, cardiac contraction is augmented in a pulse of somewhat higher tension.

The sphygmographic curve shows greater primary rise and, on account of slower pulse, a correspondingly longer systole, and epecially diastole. Sometimes great irregularity of heart action disappears. Percussion shows notable decrease in the whole area of cardiac dulness. After the bath this is less pronounced than after resistance exercises, but continues longer. Auscultation shows a varied picture; feeble heart tones become easily distinguishable, a murmur caused by relative valvular insufficiency passes through reduplication into normal tone. In other cases the stronger muscular contraction first reveals an organic murmur. Patients improve remarkably in strength and general condition. Free diuresis is induced, especially after the bath, and the general tone is much improved. Instead of the contraindications, which often limit the employment of digitalis, we have invariably induced progressive tone and strength in the whole organism, by increasing the working power of the heart on the one hand, and removing peripheral resistance on the other.

As remarked, through this treatment, the cardiac muscle becomes stronger, through receiving better nourishment. The arteries being better filled, venous congestion is relieved and the heart itself, not only receives more blood, through the coronary arteries, but also oxygenated blood of richer quality. In this way the heart stands in more prosperous relation to the organism as a whole, as its necessary muscular hypertrophy is promoted.

It is manifestly impossible to give more than general rules, which must be judiciously adapted to each individual case, as in any other treatment. We should never for a moment forget the fact, that, although these remedies are powerful and permanent in their effects for good, when wisely and judiciously administered, nevertheless, when carelessness and imprudence mark their employment, grave, and even fatal, consequences might follow.

In every strange case when we are not acquainted with the particular limitations and idiosyncrasies, we should elect to be present at both bath and resistance exercises (in case of lady patients, one could attend in an adjoining room) to supervise their effects. It may also be wiser to limit the duration of the first bath to four or five minutes, or even less. The duration of every or every other subsequent bath can be increased one minute, or rarely two minutes. After the bath the patient should be well rubbed from head to foot with a large hot bath towel until the skin is in a glow and reaction is well established. After this, it is imperative to lie in bed, well covered, in a reasonably warm, well-ventilated room, for at least an hour. Under these circumstances, the patient usually sleeps more or less soundly, and awakens much refreshed. In private establishments, where artificial baths are given, rooms must be provided where patients can rest before returning home. In Bad Nauheim patients are recommended to use wheeled chairs going and returning from the establishment. Not only should great care be observed to avoid chills and colds, by means of proper wraps, but it is necessary, and in some cases imperative, to have a trained attendant to assist the patient dressing and undressing, to remain with him during the bath, etc.

It is also imperative, in view of possible contraindications, to make a most careful and thorough examination. One should never rest satisfied until he has obtained as exact a knowledge as possible of the condition of the blood-circulatory and nervous systems, together with both family and personal history and present general condition.

Contraindications to the baths are: (1) Advanced arteriosclerosis, especially if asymmetrical, and when there has been specific infection, or family history of apoplexy, and all cases of the kind in which the baths raise instead of lowering arterial tension.

2. Chronic Bright's disease, unless advanced, is not an absolute contraindication to this treatment, although great caution would be necessary to avoid acute renal congestion and even inflammation through excessive diuresis, which both baths and resistance exercises might cause if pushed too rapidly. Advanced cases of interstitial nephritis, with constant abnormally high arterial tension would forbid the treatment. In general, when the renal disease, whether interstitial or of the parenchymatous variety, is too much advanced and very much more serious than the heart trouble, this treatment should not be employed, but secondary congestion of the kidneys, with or without albuminuria, would not contraindicate it.

3. Aneurysm in one of the larger arterial trunks would certainly forbid it.

4. Cases of bronchial asthma and chronic bronchitis would call for great caution in avoiding chills and colds, and would also dictate a milder, slower course of treatment.

5. I have never employed this treatment in cases of heart disease, complicated by pulmonary tuberculosis, but Dr. Bezly Thorne has employed the baths under these circumstances with advantage, especially when there are clubbed fingers.

6. In very grave cases of organic heart disease, in which degeneration of the cardiac muscles is too far advanced and favorable reaction could not be expected, this treatment should be omitted, at least until other remedies have been tried without success.

7. In cases of great anæmia and emaciation, while the effervescent baths are not well borne, carefully regulated mild brine baths have a most excellent curative effect. The same rule would obtain in great heart weakness or exhaustion. In anæmic subjects with fatty hearts, great prudence should be exercised in the very gradual substitution of mild effervescence in the brine baths.

As a general rule, in all grave cases when the stronger, more stimulating effervescent baths cause palpitation, difficulty in breathing (asthmatic symptoms, etc.), weakening and irregularity of heart's action and pulse, cyanosis, and other unfavorable symptoms, we should return to the mild brine baths, at least for a time.

Occasionally we observe patients with very irritable hyperæmic skins, who cannot support the slightest effervescence without suffering loss of appetite, insomnia, migraine, etc. In these cases, of course, effervescent baths should be omitted.

There are five kinds of baths employed at Bad Nauheim:

1. Simple brine baths (without carbonic acid gas).

2. Thermal baths, containing from 500 to 600 c.c. of free carbonic acid gas per liter.

3. Thermal sprudel baths (thermal effervescent) coming from air-tight underground reservoirs, containing 1000 c.c. of free gas per liter. These baths were suggested by the brothers August and Theodore Schott in 1884, but were opened only last year.

4. Sprudel baths (effervescent baths) containing 1,100–1,200 c.c. per liter

5. Sprudel strom baths (flowing effervescent) containing 1200–1400 c.c. of free gas per liter.

Of these baths, 1, 2, 3, and 4 may be imitated in private practice, according to Schott's prescription, but the surging rush and escape of effervescent water direct from a geyser spring through the bath tub, having the effect of surf bathing, would not be easy to copy by means of any mechanical device, however ingenious. (Dr. Bezly Thorne claims to have succeeded in doing so satisfactorily). In general, the latter is too stimulating for the majority of heart cases, except in such vigorous patients as require some further push of reaction at the close of their course of treatment.

In locomotor ataxia and other forms of spinal sclerosis, in certain gouty and rheumatic deposits, and in cases of postinflammatory adhesions of various kinds, it must be admitted that this bath is of unique and extraordinary efficacy.

Whether the artificial Nauheim baths are altogether as efficacious as the far more complicated natural Nauheim baths, is a question upon which there is a variety of opinions. One of the leading physicians at Bad Nauheim claims that the artificial baths have little or no value. This statement is manifestly absurd, and can be disproved by experiment.

My own experience has been that the artificial Nauheim baths and resistance exercises, when combined with vigorous hygiene, diet, etc., have almost invariably given remarkably satisfactory results; nevertheless, when possible, I insist upon the necessity of an additional course of treatment during the warmer months at Bad Nauheim. In the graver cases of heart disease, I have observed that patients usually require further treatment by means of artificial baths during the early spring months, as this is the time when relapses are most liable to occur. In this way we may confidently hope to escape complications and prevent those deadly failures of compensation which might defeat further efforts in behalf of these serious cases.

I also believe that the far more complicated natural Nauheim baths are more efficacious than any imitations of the same, however ingenious. Entire change of air and environment, enforced absence from social dissipations, business cares, overwork and worries, together with differences of diet, etc., doubtless augment the effect of treatment at headquarters

Having decided that this method of treatment is likely to prove of value in a given case, one should never be tempted to begin the same unless the patient will obey directions implicitly. Such directions should be unmistakably clear and emphatic. The diet should be suited to each particular case, but experience has taught that coffee, strong tea, tobacco, spices, and highly-seasoned dishes, all effervescent waters, effervescent wines and beer (the resulting gastric distension pressing upward would embarrass the heart's action) should be forbidden. In general, when the heart's action is much compromised, more frequent meals of highly nourishing and even predigested foods are advisable. A daily complete evacuation of the lower bowel is most important, but, on the other hand, gastrointestinal catarrh, fermentation, putrefaction, and other digestive disturbances, should be corrected by appropriate diet and treatment. Such fertile sources of some of the very cardiac conditions which we are endeavoring to cure (autotoxæmia, lowered alkalinity of blood, etc.) should be corrected before any great hope can be entertained of successful heart treatment. Physical fatigue, all excitement, worry, and business cares, should, as far as possible, be avoided. These cautions may seem fussy and even puerile, but I have seen the very object of the treatment defeated by lack of attention to such detail. In a case in which the balance of vital resistance is often so compromised that our margin at best is perilously narrow, we cannot afford to squander any help, however small, in our endeavor to promote repair and cure.

The Artificial Baths.—To imitate the brine bath, we begin with a solution of 1 to 1½ per cent. of common salt, and 1 to 1½ per 1000 of chloride of calcium at a temperature of 33.5° C. (92° F.). In feeble anæmic subjects, who suffer from cold extremities and have very little reaction power, we may at first prescribe baths at a temperature of 35° C. (95° F.), but this is the limit at which we can hope for any tonic reaction. Warm (I do not mean hot) baths would rather cause lowering of blood-pressure, and at the same time depress the heart's action.

Obviously, the duration of the bath must depend, at first, upon the reactive power of each individual patient, but in general three to seven minutes would be the average limit of time.

Observing always the individual indications already mentioned, as a general rule the cooler baths have a far greater tonic effect. As the cure progresses, it is better to prescribe cooler and more concentrated baths, even if of shorter duration, for more sensitive delicate subjects. It is imperative the bath-room should be warmed in cold weather, and in any case it should never be cooler than 65° to 70° F. At first, baths should be given every other day, increasing usually one minute every or every other time, but later, two and even three baths may be given in succession. The bath may be also ½° C. cooler every or every other time. The strength of both solutions may now be gradually increased, either by addition or Nauheim salts, which can be obtained in the market, or by increasing gradually the chloride of sodium to 2 or 3 per cent. and the chloride of calcium to 2 or 3 per 1000. Owing to the great difficulty of procuring the Nauheim salt in Italy, where salt is a government monopoly, I now employ the latter method. I must frankly confess, however, that I have never observed such noteworthy difference in effect between the two as would warrant the additional expense of the Nauheim salt.

The Thermal Bath.—After a certain number of brine baths (5 to 10) we may begin the so-called thermal bath, which contains a certain percentage of carbonic-acid gas in solution. It may be prepared, according to Professor Schott's prescription, with crude hydrochloric acid and bicarbonate of soda. Latterly, I have employed cakes of bicarbonate of sodium, and cakes of crude sulphuric acid, mixed with sulphite of sodium. With these one can produce a vigorous effervescence lasting a full hour. Another method has been devised to imitate the effervescent bath by employing water charged under pressure with liquid carbonic-acid gas.

This bath may be given, at first, at a temperature of 32.5° C., but no longer than seven or eight minutes, increasing duration and diminishing temperature, as in the brine bath and effervescent bath.

The Thermal Effervescent Bath.—After a certain

number of the so-called thermal baths (fifteen to twenty) we may begin the so-called thermal effervescent bath. This is prepared by placing a certain number of the cakes above mentioned (alkaline upon acid) at the head, middle, and foot of the bath tub in the prepared brine water (this should contain 2½ to 3 per cent. common salt and 2½ to 3 per 1000 of chloride of calcium). The patient then enters the bath during the effervescence. To produce the effervescent bath, we increase the number of cakes.

Whether it is an advantage or not (which may be discussed later), one can produce almost any degree of effervescence in the artificial bath by increasing or decreasing the quantity of material for that purpose.

This bath may be given at first at a temperature of 32.5° to 31.5° C., but no longer than seven minutes. Even the cooler baths at end of course should rarely be cooler than 28° to 29° C. Eight to twelve of these baths may be prescribed.

One precaution is imperative, viz., to avoid inhalation of carbonic-acid gas by ventilating the bath-room and keeping the patient's head well above the water otherwise very unpleasant consequences might ensue. In thermal or effervescent baths full immersion causes great dispnœa at first; it is advisable that the chest remain free. The so-called English bath-tub with sloping end for the head is the best and safest. When this cannot be obtained, a cushioned board of appropriate shape may be employed.

The obvious question, how long a course of baths would be advisable in a given case, can be answered only in a general way, depending upon the condition of the nervous as well as circulatory system, and upon the discretion of the physician. Sometimes not more than fifteen to eighteen graduated baths can be given without risk of causing unfavorable reaction. Again, in robust subjects, thirty to thirty-five are not only well borne, but absolutely indicated in order to obtain maximum good results. When patients complain at any period of great nervous irritability, insomnia, debility, etc., which symptoms do not improve under appropriate treatment and interval of rest, then a change to more bracing air should be prescribed. It cannot, however, be too strenuously urged that patients with feeble, dilated hearts, with or without arterial or cardiac degenerative changes, should never be sent to even moderate heights, because such altitudes almost invariably cause dangerous increase of arterial tension. I cannot better emphasize this important fact than by quoting lines from a letter (a constant experience) just received from a patient:

"I think the place must have been too high (St. Beatenberg, 3770 feet), for I felt much worse each day and had much pain about the heart, down the left arm, and up the left side of my throat. I also began to get breathless again, my muscular strength seemed to give way and I had a good deal of indigestion. I then came down here (Meirengen, 1968 feet), where I certainly feel better." This patient had derived great benefit from the baths, and it seemed a pity to sacrifice so much upon the altar of altitude. In another case of double valvular lesion, the patient went to a height of over 5000 feet "in order to cure a bronchitis before coming to Bad Nauheim." This patient arrived with dangerous pulmonary congestion, at both bases, and other unfavorable symptoms as a consequence of that imprudence.

A well-known physician, who holds a government appointment in the tropics, came to Bad Nauheim to consult Professor Schott, in the summer of 1900, from an altitude of 4000 feet for his first series of baths. His heart was feeble and much dilated; there were degenerative myocarditis, stenosis of the aortic valvular orifice, albuminuria, due to secondary renal congestion, etc. The blood-pressure was extraordinarily high (220 to 230), measured by Gärtner's tonometer). The patient complained of intense headache and great dyspnœa. After appropriate treatment and a course of baths, the patient returned to his tropical post much improved, "remaining fairly well during a busy season's work." In the summer of 1901 he repeated the same imprudence, coming to Bad Nauheim from an altitude of over 5000 feet. He had a long and dangerous illness, nearly losing his life in consequence, and was unable to take the baths. Of extraordinary interest in connection with this case is the fact that when all the usual remedies had at last failed to relieve, and the patient was nearly moribund, Dr. Bezly Thorne suggested trial of the Schott resistance exercises, which he administered himself. The improvement from the first was amazing. Not only was the patient relieved of all the agonizing and dangerous immediate symptoms after a few days, but he made such satisfactory progress that, after a few weeks, he was able to travel.

Several unprejudiced heart experts, who observed the effect of this treatment, and had seen the case previously, were unanimous in the opinion that timely recourse to this method of treatment undoubtedly saved the patient's life. It was a great object lesson.

The Schott Resistance Exercises.: (1) With assistance; (2) Self-resistance.

I again venture to refer to Dr. Bezly Thorne's book for a graphic description of the Schott resistance exercises. It is advisable for every physician to learn and practise them so that he can authoritatively correct carelessness and rashness on the part of the attendant who administers them to the patient. The resistance should be such as the patient can readily support and overcome without strain or fatigue, and each movement should be carried out with clock-like regularity and smoothness. The slightest strain or jerk would defeat the very object of the exercises, viz., to stimulate the heart to slower, stronger contractions through reflex action. The patient meanwhile should not only breathe naturally during the whole series of resistance movements, but should also experience a sense of relief in breathing and a general feeling of well-being. There should, in some cases, at least, be as long an interval of rest (sitting) between each movement as it takes to complete the same. The patient's own statement regarding fatigue should be accepted, and a little care in watching nose and mouth will give warning of dispnœa, or even quickened respiration. This will not only teach caution as to speed and amount of resistance, but also warn us when to adjourn the exercises to another occasion. By and by, in certain cases, the whole series of exercises may be repeated at the same sitting, but under no circumstances should the same movement be given twice in succession. At first it may be necessary to give a part or all of the exercises in a sitting, or even in a reclining position. We should omit raising the arms above the shoulders and the trunk exercises, when the feeble heart is much dilated. If these precautions are observed, one rarely meets with contraindications to the exercises and rarely has the slightest difficulty in employing them. Indeed, in both baths and exercises, it is of the highest importance to have a just and clear notion of what can be accomplished, and to know, as far as possible, the why and wherefore. In this way contraindications

and limitations become so clear and positive that one is not likely to become discouraged, through perpetrating avoidable mistakes, nor led to condemn the method.

Many physicians and most laymen, are incredulous that these simple resisted movements should have any effect upon the heart, except perhaps to fatigue it, in feeble subjects. It is easy to demonstrate to physicians, however, that we are able to produce favorably tonic effects upon the cardiac and general muscular systems, and indirectly upon digestion, etc., by means of various carefully graduated resistance exercises in orderly series, whereby almost every voluntary muscle in the body is called into active contraction and relaxation.

Some of the great advantages of these exercises are: (1) That they can be given in bed or sitting, before the baths could be considered safe, thus serving as preliminary tonic treatment. (2) They can, and in my judgment should be, continued indefinitely. (3) They can be modified to suit almost any indication of general strength or debility. (4) Patients of even moderate strength can learn these self-resistance exercises and thus do without attendants. (5) They are admirable respiratory exercises; the patients learn to stand more erect after a time and to breathe more deeply, the chest measurements increase, the general muscular tone, digestion, etc., improve. (6) A constant tonic influence upon the heart muscle, maintained from day to day, must eventually prove of great therapeutic value. (7) Of course, it must be insisted that no heart case can do without a certain medical supervision.

Nevertheless, to obtain best results, a combination of baths and exercises is necessary. In general, it must be admitted that the baths take up the work where the exercises can go no further, and through opening up even closed peripheral circulatory channels, powerfully stimulating metabolism in general (their beneficial effects upon certain gouty and rheumatic conditions might be mentioned), inducing beneficial trophic changes, and in many other ways, continue to produce profounder and more permanent curative effects.

One should patiently, persistently, and methodically strive from day to day for future results, knowing well that no great good can be accomplished in haste.

To prescribe effervescent baths of longer duration (10 to 20 minutes) at first is a radical mistake which must be condemned. On the other hand, all dawdling, pottering, half-hearted employment of these methods of treatment, under guise of scientific advance, is vicious, if not contemptible. The necessity for great care and prudence cannot be over-emphasized, but, on the other hand, one should steadily and boldly, even if slowly, advance upon right lines. A wise general nourishes and saves his soldiers in every possible way, but pushes them rapidly and surely toward a vulnerable point of attack. Nothing can be worse than rashness, when circumstances dictate prudence, or halting timidity, when courage and boldness alone can win the day.

Case I.—Mitral stenosis, great dilatation of both right and left ventricles, congestion of both lung bases, œdema of legs and thighs, renal congestion, albuminuria, hyaline casts, hepatic congestion with slight icterus, anæmia (hæmoglobin 57 per cent., red blood corpuscles 3,400,000), moderate enlargement of spleen.

German shop girl, twenty-seven years of age, sent to me before she had any treatment at Nauheim, in December, 1896, by Professor Schott, for treatment in a warmer climate. She arrived nearly moribund, and was carried on a stretcher to bed in a boarding-house. She was dangerously ill several days, slept only in snatches; arms, feet, and lips, were cyanotic, she had extreme dyspnœa, was barely able to talk hoarsely and spasmodically, pulse feeble, thready, irregular, 120; arterial tension 80 mm. of mercury; I could not obtain a satisfactory sphygmographic tracing. The total quantity of urine in twenty-four hours was 720 grams; it contained bile salts and bile pigments, as well as albumin, hyaline casts; the patient had a dry skin, obstinate constipation, with canary yellow and very offensive fæces.

Dry heat (180° F.) was at once applied over the heart (Theodor Schott method), and cutaneous friction with hot cloths, stimulants, frequent feeding with concentrated predigested foods, heart tonics, etc., were ordered. The patient could not take digitalis over thirty-six hours without poisonous effects. Minute doses of calomel and bismuth were also given to disinfect the bowels, with satisfactory results. On the fourth day, the patient having rallied, resistance exercises were cautiously administered in reclining position, and continued daily with marked benefit until twelfth day, when the first bath was given of 1 per cent. of common salt and 1 per 1000 chloride of calcium at a temperature of 35° C., four minutes' duration. The patient was lifted in and out of the bath, and the reaction was most satisfactory. Pulse, before, 108; after, 96; one hour later, 88, fuller and stronger. Arterial tension 84 mm. before, 104 one hour after bath. The total circumference of cardiac dulness diminished one-half inch in every direction. Second bath was given after forty-eight hours' rest, at a temperature of 34.5° C., duration five minutes.

The combination of baths and exercises was continued seven weeks, when twenty-eight baths had been taken (20 thermal and 8 effervescent). The improvement in the patient's condition at this time was simply amazing; she had gained ten pounds in weight; could walk out, twice daily, considerable distances without breathlessness or fatigue, and even climb stairs without unpleasant symptoms. She slept the night through and awakened refreshed. The bowels were regular and stools normal. Appetite and digestion were excellent. Former vertigo had disappeared. Anæmia was much improved (hæmoglobin 84 per cent., red blood corpuscles 4,000,000). I could not discover any enlargement of spleen. Liver congestion had disappeared; apex beat was in line with the nipple; heart dimensions showed hypertrophy, but no marked dilatation; pulse 74, stronger, fuller; arterial tension 120 to 130 mm. of mercury; no pulmonary congestion whatsoever, and no discoverable signs of renal congestion; urine normal in quantity and quality, no œdema whatsoever; patient's complexion rosy and skin clear, eyes bright, and step elastic. Resistance exercises were continued another seven weeks, when patient learned self-resistance exercises. Owing to lack of funds, she was compelled to return to her own damp climate and take up her work again. She continued in good condition two years longer, with help of one course of baths at Bad Nauheim, since which time I have had no further news.

Case II.—Fatty degeneration of heart, œdema of both legs, constipation and flatulent indigestion, great dyspnœa, very irregular heart's action (pulse 90 to 120), anæmia (owing to her unexpected departure, I was unable to examine the blood); urine scanty, concentrated, loaded with urates, specific gravity 1032, but albumin, sugar, and renal débris were absent; the skin was dry. At this date (May, 1899) there was no pulmonary congestion, although

the patient said that "she was liable to attacks of bronchitis in bad weather." She had had obstinate insomnia for over two years.

American lady, fifty-four years of age, rather stout, had been failing in health some years, and latterly had been compelled to lead an invalid life. As I could see patient but once before her departure, I gave specific directions regarding diet and hygiene (forbade liquids with meals and limited daily consumption of hydrocarbons), prescribed for constipation, and advised cure under Professor Schott at Bad Nauheim. The patient took two courses of baths (24 baths each), with six weeks interval at a bracing mountain resort of moderate altitude (1800 feet). I examined this patient at Bad Nauheim, a few days before she finished her second course of baths, and discovered a great improvement in every respect. Pulse was stronger, regular, 76, heart sounds were distinct and well accentuated, and the apex beat was within the nipple line. No dilatation, œdema had entirely disappeared, no flatulency, no indigestion, urine abundant, specific gravity 1020. Patient had improved remarkably in appearance, skin was clear and rosy, eyes bright, figure more erect. Patient could walk easily without fatigue, had good appetite, and slept well. The patient returned to Rome and continued in good condition the whole season, meanwhile did not require medical attendance, although she continued resistance exercises, diet, and hygiene.

During the summer of 1900 she also took two courses of baths, with the same interval between, in a mountain resort, and returned to Rome in even better condition than the year before. She was very well during the winter, continuing resistance exercises, diet, and hygiene with massage part of the time. In April, after a period of great anxiety, with distress of mind lasting two months, the patient sent for me on account of palpitation and breathlessness. I found the pulse very rapid but not irregular (120), heart sounds distinct, clearly accentuated, apex beat within nipple line, easily discoverable upon both inspection and palpation, no œdema, slight dilatation of the right ventricle, rather severe flatulent indigestion. Patient had neglected diet and hygiene and resistance exercises for nearly two months on account of "worries." As the tachycardia was clearly of nervous and digestive origin, I ordered small doses of strophanthus; the patient resumed exercises, diet, etc. Owing to improvement, the drugs were omitted in ten days and patient continued to gain, until she took her usual summer courses of baths at Bad Nauheim (1900). I had occasion to examine her there in September, and found her condition most satisfactory in every respect.

This remarkable change from hopeless chronic invalidism to reasonable health, strength, and cheerful, useful life is more inspiring than much unfruitful theory. This case also illustrates the great importance of continuance in "physical righteousness." If such patients lapse into slothful unhygienic habits, one can predict a pretty certain relapse of former degenerative changes, sometimes of more intractable character.

Case III.—First saw this patient in November, 1896. The case was one of cardiac hypertrophy with considerable dilatation, great arterial tension (190 to 200 mm. mercury), gouty kidneys, rather advanced arterial fibrosclerosis, intense headache, agonizing dyspnœa, œdema of legs and thighs, beginning ascites, urine scanty, considerable albumin, both granular and hyaline casts, renal epithelium; pulse very irregular, heart's action irregular, tumultuous, and labored; liver enlarged.

The patient, a retired English army officer, fifty-nine years of age, had served many years in tropical countries, had had cholera in India, over twenty years before, also typhoid fever still earlier; several attacks of tropical dysentery at various times; once had jungle fever, contracted hunting tigers. Within the past five years he had had semi-annual attacks of acute gout in the right foot. The patient had large frame, powerful muscular system, had been noted for his powers of endurance; he had always been temperate in eating, and, although he had always taken whiskey with lunch and dinner and upon going to bed, had never consumed more than "six to eight ounces daily." When gout began, the whiskey was stopped, and since that time he had been a total abstainer. He dates present illness from a chill in the early summer. Since then has been growing gradually worse, and latterly has not been able to leave his room. As he had no appetite, suffered from nausea, and was very thirsty, he had been taking from three and a half to four liters of cold milk daily, and frequent sips of cold water. Upon accurately measuring total quantity of liquid consumed in twenty-four hours, it was found to be from 4000 to 4800 grams. At the same time he was passing from 860 to 1240 grams of urine with a comparatively dry skin. A simple arithmetical calculation will show where the superfluous liquid was being stored, without delaying to discuss Oertel's theory of what occurs in these cases.

He was ordered one liter of milk and 500 grams of distilled water, in divided portions daily, and frequent meals of predigested foods. His record of urine passed during the next eight days is as follows: First day, 1320 grams; second day, 1640 third day, 1830; fourth day, 2620; fifth day, 2300 sixth day, 1920 (then two days were very cold and stormy); seventh and eighth days, 3800 grams From this time until the œdema entirely disappeared and the hydrostatic balance was restored, as the patient was less thirsty, he was allowed 1300 to 150 grams of milk daily in addition to other food and bit of ices, but no more water than sufficient to balance the output.

Arterial tension had now decreased to 130 to 12 mm., and there was no further nausea or digestive disturbance. As the heart's action, however, still left much to be desired, moderate doses of digitalis with nitroglycerin were ordered, together with full doses of strychnine. Under this treatment the patient continued to improve slowly, in spite of inclement weather, until February 20. He then insisted upon taking artificial Nauheim baths, "as a friend had derived great benefit from them under similar circumstances;" as there was a reasonable prospect of his deriving benefit from this treatment I consented.

He took the first bath February 20 at a temperature of 35° C., duration four minutes, and expressed himself as feeling better after it. Pulse, before, 96 after, 90; one hour later, 90, still irregular, but rather stronger. Heart's area of dulness slightly decreased. Blood-pressure, before, 120 mm.; one hour later, 11 mm. (Sphymographic tracing of this and other cases will be given upon another occasion.)

February 2, took another bath at a temperature of 34.5° C., duration five minutes; result not noticeably different from that of the first bath. Patient was always enveloped in hot sheet and well rubbed after bath, then put to bed. The baths were continued cautiously (patient meanwhile did not leave the house) until the 18th.

Bath March 28 at a temperature of 31° C., duration twelve minutes. Patient at this time was cheerful and felt much better. There had been a slo

but undoubted improvement in his general condition. Area of cardiac dulness at least ½ inch less than at first; pulse 88, much less irregular and stronger. His appetite had improved, no indigestion, less dyspnœa, urine abundant, specific gravity 1016, albumin less, much less renal débris, no headache, no trace of œdema, excretion of urine increased.

It was decided to give the patient two more baths, and then begin the exercises. The attendant now made a dreadful and incomprehensible mistake, upon the first and only occasion when I was not present at the bath. I might say that in all cases I invariably prepare for each bath, the day before, plainly labeling package of salts, with description of contents, temperature and duration of respective bath, hour, and date. In this instance, orders had been given to delay the bath until my arrival, but, unfortunately, the patient would not wait, and the attendant prepared the bath. With incredible stupidity (I afterward discovered he was drunk), the man procured 3000 grams of chloride of calcium, and 300 gms. of chloride of sodium at the nearest pharmacy; although the appropriate package was in its usual place and properly labeled, the bath thermometor lying beside it. The attendant naturally enough, not finding this bath thermometer, took a self-registering instrument (F) from the wall. He "guessed that to reduce that scale to this, one would multiply by four" (132° F.). I arrived about fifteen minutes after the bath had been given (meantime messengers had been hunting for me). I found patient in deep coma, skin almost parboiled, radial and brachial arteries hard round wires, pulse hardly discoverable, temperature in rectum 101° F., heart's action tumultuous, irregular, and very feeble. There had been a copious involuntary evacuation of bowels, the face was purple, Cheyne-Stokes respiration, etc. Meanwhile I had given a hypodermic injection of nitroglycerin, which was repeated every fifteen minutes until reaction was obtained, ice cap to head, diffusible stimulants per rectum, sponging surface of body with tepid water, warm mustard foot-bath. Patient slowly rallied under this treatment, and at midnight following was conscious and had passed urine pretty freely, temperature in rectum normal, pulse 96, blood-pressure 180 mm., respiration 20 and regular, heart's action irregular but no longer tumultuous, much stronger, perspiring freely; skin pink color. Patient continued to improve, and on April 20 was apparently in as good condition as before the accident. In the latter part of April he contracted influenza, which was then epidemic, developed pneumonia, and died after a few days' illness.

I have reported this case at length for two reasons: (1) To demonstrate that, although the artificial Nauheim baths may sometimes be prescribed with benefit in this class of cases, nevertheless, extreme care and prudence are necessary. (2) Even grave accidents are not necessarily fatal, but one should always employ a trained nurse to assist in giving these baths, even when the physician elects to be present. (3) Failures are often more instructive than success.

25 Via Gregoriana.

Nasal Disease.—The indications for operative treatment depend on both the subjective and objective symptoms. A noticeable inadequacy of either nasal passage, the presence of excessive or retained secretion, or an abnormal redness of the mucous membrane at any point, are all evidences of abnormality, which, if coupled with inconvenience to the patient, invite corrective attention.—Edw. Pynchon.

CONTRIBUTION TO THE STUDY OF SPONDYLOZE RHIZOMÉLIQUE, WITH REPORT OF THREE CASES.*

By ALFRED GORDON, M.D.,
PHILADELPHIA.

INSTRUCTOR IN NERVOUS DISEASES, JEFFERSON MEDICAL COLLEGE; ASSISTANT VISITING NEUROLOGIST TO PHILADELPHIA HOSPITAL; NEUROLOGIST TO DOUGLAS MEMORIAL HOSPITAL.

The original reports of Bechterew (1892), Strümpell and Marie (1898) concerning the disease, the chief feature of which is rigidity of the spine, showed at the time of their publication that there were two distinct forms: one, ankylosis of the cervical portion of the spine with meningomyelitis; the other, an ankylosis of the spine and of the large proximal joints of the extremities without cord involvement.

The etiological factors, as well as the clinical pictures, of the two types of the disease were then sharply defined. Traumatism with an hereditary predisposition, sudden onset, a limited kyphosis with ankylosis, which is not generalized and does not involve the limbs—briefly, a condition which is primarily and strictly localized to the upper portion of the spine, such is Bechterew's disease, to which Marie gave the name heredo-traumatic kyphosis.

The disease described by Strümpell as "chronische ankylosirende Entzündung der Wierbelsäule," and later by Marie as "Spondyloze rhizomélique," is a pathological condition which has apparently nothing to do with the first form. As the name implies (σπόνδυλος—vertebra, ῥίξα—roof, and μέλος—limb.) This affection is essentially a general disease involving, not only the entire spine, but also the limbs.

Bechterew, in his cases, found a degeneration of the roots and of the posterior columns in the cervicodorsal region of the cord with a thickening of the pia and atrophic changes of the spinal ganglia. He therefore concluded that the rigidity and kyphosis were due to an insidious and gradual degeneration of the roots and to a paretic state of the muscles of the spine, which developed secondarily to a chronic lesion of the meninges. In spondyloze rhizomélique of Strümpell-Marie's type no trace of an inflammation of the meninges was found, and consequently there is no question of an organic involvement of the nervous system. The post-mortem findings, as seen from the elaborate description given by Léri (*Revue de Médecine*, 1899, p. 597), consist of an ossification of the pericarticular ligaments of the spine and hypertrophy of the articular processes which come into immediate contact with each other after the last vestige of the cartilages has disappeared.

Two distinct types of spondylosis were therefore created. At first various writers followed Bechterew, Marie, and Strümpell and reported cases that came under their observation as belonging to either of these two types. Although in both affections a pathological condition, resembling to some extent the chronic deformant rheumatism, was found, nevertheless the latter disease was considered to be different from spondylosis.

Very soon, however, this view became untenable. Transitional forms between the two extreme types had been observed, also cases in which the small joints of the limbs took part in the process of ankylosis (Lichtheim, Jacoby, Beckman, and others), so that, at present, the old view counts very few partisans.

According to some, Bechterew's spondylosis, as well as Strümpell-Marie's type, including also the intermediary forms, are not autonomous affections or morbid entities, but, on the contrary, present a pathological unity and belong to the domain of

*Read before the Philadelphia Neurological Society.

deformant polyarthritis (Saenger, Oppenheim, Senator). Other writers do not accept the view that arthropathies of all possible varieties have only one etiological factor, they believe that the etiology is various; alongside of chronic rheumatism—heredity, physical, toxic (Hoffman, Léri), infectious (Marie, Raymond, Bäumler), and trophic elements may play an important rôle. We must recognize, however, that while there are really cases of rigidity of the spine in which a rheumatic history is evident, also cases in which chronic deformant polyarthritis is present, there are nevertheless cases in which the rheumatic etiological factor is totally absent. The tendency of some writers to consider the affection as a variety of arthritis deformans for the only reason that the spinal column is rigid, is in our opinion erroneous.

The pathological anatomy of the cases reported as belonging to Strümpell-Marie's type or to Bechterew's type is not at all convincing for considering the disease as one of rheumatic origin. Besides, the clinical picture, course, duration, and termination of the affection is by no means in every case identical with that of rheumatism, and this is particularly true with regard to Bechterew's disease.

Whether the disease is the expression of a general articular rheumatism or is an autonomous affection, as Bechterew, Strümpell, and Marie wanted, it is difficult to say, as the etiology of rheumatism itself is not at all known to us. If, therefore, the idea of uniting all forms of spondylosis in one cannot reasonably be accepted, the other tendency of describing and classifying all forms of spondylosis under only two types cannot be equally considered.

It is certain that there are cases which belong at the same time to Bechterew's type and to Strümpell-Marie's type. The reason of it lies probably in the fact that the morbid agent, whatever it may be, affects certain portions of the body and certain periarticular tissues more than others.

The first case I am about to report is one in which you will find on one hand meningomyelitic symptoms of Bechterew's disease and spondylosis of Marie's type, and, on the other hand, an involvement of the small joints of the hands and face, a fact not observed in either disease. The patient never had rheumatism. The second case is also lacking entirely in a rheumatic element. The third case, although with a history of rheumatism, shows nevertheless the onset of spinal rigidity immediately after an injury with a gradually progressing course.

Case I.—Mrs. L. S., aged fifty-four years, colored, was admitted to the Douglass Hospital on July 8, 1903, and gave the following history:

About a year ago she had an attack of vertigo with loss of consciousness, after which she was unable to walk and her vision and speech became markedly impaired. Since then she had several attacks of the same character, which occurred only after exertion. At the same period she noticed for the first time a rigidity of the spine which came on without pain. The rigidity gradually increased and invaded the joints of the extremities. Dr. Mossel, her attending physician, states that five years ago he noticed a gradually coming on ataxia in the lower extremities and about eighteen months ago the arms also became ataxic; she had great difficulty in carrying her hands to the mouth (there was evidently rigidity and limitation of movements of the joints of the arm). Within the last year she developed very frequent micturition (every ten minutes), with occasional incontinence and involuntary defecation.

Status præsens.—The general appearance of the patient is that of a much older person. The large as well as the small joints of the four limbs are ankylosed to some extent, but not enlarged. The spinal column is extremely rigid, so much so that the patient's attitude while standing, walking, or sitting is markedly straight and gives the impression of her wearing an orthopedic corset. When she attempts to sit down, the trunk does not bend but drops down as one mass. When she attempts to turn, she cannot do it easily, the whole trunk turns. Leaning forward or backward is absolutely impossible, lest she will fall. In walking, the body is erect and the knees do not flex; the steps are very small and the feet scrape the floor. Arms are in a semiflexed position, can be raised only to some extent and with difficulty. There is marked resistance to passive movements of individual joints of the upper extremities. The lower extremities are in a semiflexed position; patient experiences the greatest difficulty in crossing or in extending her legs. The right arm and leg were affected with a peculiar movement; patient would incessantly move her hand toward the mouth and the right leg across the left. However there were no clonic or tonic contractions. The head and neck are rigid, cannot be turned to either side or rotated, even passive movements of the head are met with considerable resistance. The face is immovable, mask-like, all the muscles of it are affected with the same rigidity; laughing, or even smiling, is impossible, neither can the patient frown or wrinkle her forehead. Mastication is markedly impaired, but there was no evident disturbance in the act of deglutition. The speech being normal, as far as the power of articulating is concerned, was nevertheless very indistinct, because of the patient's inability to separate the lips or to bring them in contact rapidly enough, also because of the rigidity of the auriculotemporal articulation and of the entire musculature of the face. Respiration was short and abrupt; there was very little expansion of the thorax. The considerable emaciation of the body showed distinctly the contour of the individual muscles. They resembled cords in a state of extreme tension. The latter was particularly noticeable on the neck and limbs. On passing the hand over her back one gets the impression of a hard and solid mass covered with skin and divided in two halves, between which is placed the inflexible spine. Briefly speaking, the patient resembled to a very great extent a manikin animated with some voluntary movements.

The examination of the nervous system gave the following result: Mental condition was good. Vertigo was frequent, especially on the least exertion. No headache. The eyes presented distinct Argyll-Robertson pupils, but no changes in the fundi. The gait was markedly ataxic and spastic. Romberg's sign present. Ataxia was also present in the upper extremities, which were also affected with a fine passive tremor. The latter increased to a great extent at each voluntary act. The deep reflexes in the upper as well as in the lower extremities were all exaggerated. Ankle-clonus was present only on the right side. Babinski only on the right. The reflexes of the face were also much exaggerated. The mechanical irritability was greatly exaggerated in all the muscles of the body. Reaction of degeneration was present in all the muscles of the extremities, in other muscles the electrical response was very pronounced to weak currents. In spite of their rigidity, the majority of the muscles were animated with fibrillary contractions, which were particularly marked in the arms. The muscular atrophy was not uniformly distributed and had all the appearance of Aran-Duchenne's type as far as the upper extremities are concerned. Sensory disturbances were not marked; only a diminution

of sensations could be elicited. On the other hand the patient presented a distinct girdle sensation, at times sharp, shooting pains in the arms and legs, but continuous drawing sensations in the legs. The sphincters of the bladder and rectum were greatly involved. Involuntary defecation and micturition, and particularly the frequent micturition, disturbed the patient to such an extent as to make her life intolerable.

The examination of the circulatory system revealed pronounced arteriosclerosis, accentuation of the second aortic sound, and a rough first sound at the apex. Urinary examination showed no pathological elements chemically and microscopically. Such was the patient's condition at the time of her admission to the hospital at the beginning of July. Nitroglycerin, iodides, minute doses of strychnine and digitalis, in addition to an appropriate diet, was the treatment patient had. The rigidity, ataxia, difficulty of mastication and of speech, general wasting and weakness continually increased, when, about the middle of August, through some imprudence in the diet, the patient was taken with a diarrhœa. Although the latter was immediately arrested, the patient grew weaker every day, and the rigidity of the muscles of the face increased to the extent that the patient ceased to speak and eat. The swallowing became difficult, the incontinence of urine and of fæces became extreme, two bedsores appeared in the middle of the sacrum. Soon the bedsores began to suppurate, the temperature which had been always normal rose to 101° and two days later the patient expired. An autopsy could not be obtained. To sum up the case presents an example of spondylosis which could not be placed among those of Bechterew's type. The only resemblance with the latter is found in the presence of cord symptoms.

FIG. 1.

However in Bechterew's disease the onset of the rigidity of the spine is preceded by root pains, while in our case the pain in the extremities appeared much later after the rigidity. Moreover in Bechterew's type the meningomyelitic symptoms are limited to the upper portion of the body, while in our case the nervous symptoms pointed to an involvement of the entire cord. The most important differential point lies in the localization of the rigidity: our case presented an involvement of all the intervertebral articulations and of almost all the joints of the body, while in Bechterew's type the cervicodorsal portion alone is invaded. Is our case a pure

FIG. 2.

example of Strümpell-Marie's spondylosis? The rigidity of the whole spine with involvement of the largest joints of the limbs makes the case as one of spondyloze rhizomélique. The involvement of the small joints of the extremities with those of the head, the clinical picture of ataxic paraplegia and marked involvement of the sphincters, plus Argyll-Robertson pupils, are symptoms not observed in Strümpell-Marie's type. Finally the amyotrophy with increased mechanical irritability, fibrillary contractions and reactions of degeneration are symptoms observed in spondyloze rhizomélique. Our case therefore can be recorded as one of spondylosis of a mixed variety, and illustrates once more the impossibility of recognizing only two extreme types of the affection. In view of the fact that there was no history of rheumatism previous to the onset of the spondylosis and of the cord symptoms, we have no sufficient ground to ascribe the disturbances to a rheumatic agent.

CASE II (Fig. 1) presents a great many spine and cord symptoms similar to the first case and there is no history or any evidence of rheumatism. The history is briefly as follows:

P. M. A., aged fifty-four, sustained fifteen years ago an injury by falling from a load of hay and striking his neck and head. Intense paid followed and was soon accompanied by muscular wasting and twitching. The disease progressed steadily and soon rigidity with marked limitation of movements developed in the cervicodorsal region of the spine in the large proximal joints. At present time he shows, in addition to the rigidity of the entire spine and a kyphosis of its cervico dorsal portion, all the typical symptoms of an amyotrophic lateral sclerosis plus involvement of the sphincters.

The history of trauma and the cord symptoms

would suggest here Bechterew's disease, but the involvement of the spine with the large proximal joints would place the case in Strümpell-Marie's type. This is therefore again a mixed type, in which there can be no question of a rheumatic agent or arthritis deformans as an etiological factor.

Case III (Figs. 2 and 3, from Dr. Dercum's service in Philadelphia Hospital).—S. F., aged forty-three, sustained an injury of the neck thirteen years ago. On the following day pain and stiffness appeared in the neck, which kept on increasing. At the end of three years the entire spine was rigid. At that time the stiffness also involved the hip-joints. During the first few years patient had several attacks of rheumatism in various articulations, but each attack lasted a short time. In the meantime the rigidity of the spine and hip-joints progressed. Examination showed prominence of the vertebræ from scapulæ to sacrum, head bent forward and downward, scoliosis, the joints of the hands

Fig. 3.

deformed and the large joints ankylosed, the muscular wasting is extreme and unequally distributed, fibrillary tremor, increased mechanical irritability and reactions of degeneration in the majority of the muscles. The tendon reflexes of the left upper extremity are increased, knee-jerks lost on the left and elicited with difficulty on the right, tendo Achilles reflex is lost. In this case therefore a history of rheumatism is present, but it is very peculiar to notice that the same rheumatism before the accident never affected the vertebræ. Immediately after the accident, during which he struck his neck, the rigidity of the spine commenced to involve also the large proximal joints. It is also interesting to note that while in the first two cases the reflexes were exaggerated, as is usually the case in spondylosis, here the reflexes are absent. This is again an example of an association of Bechterew's and Strümpell-Marie's types.

We are now in possession of facts showing that there are multiple conditions which are apt to produce limitation of movements and rigidity of the spinal column as well as of other articulations. Tabes, syringomyelia, spinal muscular atrophy, interstitial hypertrophic neuritis, diseases of the muscles, as myositis, hypertrophic cervical pachymeningitis, chronic deformant rheumatism with gout—are diseases which at a certain period of their development may give more or less the picture of both Bechterew's and Marie-Strümpell's types. The degree of resemblance to the latter will depend upon the intensity of the diseased process. Taking, therefore, into consideration the presence of a great many transitional forms and the fact that other conditions may give a rigidity of the spine with or without cord symptoms, it seems exceedingly doubtful if the disease under discussion be considered as a pathological entity. It seems more rational to reserve the term spondylosis only for the purpose of designating the symptom—rigidity of the spine—and the original names given by Bechterew, Strümpell, and Marie be abandoned. In conclusion I will say that the object of this report is to show that:

1. While Bechterew's, as well as Strümpell-Marie's, ideas cannot be accepted in the sense of the existence of two sharply defined clinical entities, the other view of considering all cases of spondylosis as an expression of rheumatism for the simple reason that the patient some time during life presented a history of rheumatism cannot be equally accepted. The onset, course, and termination are in some cases not those of rheumatism.

2. A great many cases recorded, if not all, present distinct symptoms of cord involvement showing that the etiological factor is of a more complicated order than one may suppose.

3. Between the types described by Bechterew, Strümpell, and Marie there are a great many intermediary forms.

4. Spondylosis is only a symptom of a more complicated disease, the etiological factor of which is not at all elucidated.

I wish to thank Dr. J. O. Arnold for the photographs.

THE ANTISEPTIC TREATMENT OF PNEUMONIA IN INFANTS AND CHILDREN.

By S. HENRY DESSAU, M.D.,
NEW YORK.
PROFESSOR OF PEDIATRICS, NEW YORK SCHOOL OF CLINICAL MEDICINE.

At a recent notable discussion on Pneumonia in Infants and Children that was held before the Pediatric section of the New York Academy of Medicine, the main drift of the discussion was toward the treatment of the disease. And yet it was the unanimous opinion of those who participated in that discussion, that the disease, especially the lobar form, was a self-limited one, and tended normally to recovery even under the most opposite conditions of treatment. Dr. Bovaird gave a most able review of the pathology of the two varieties of the disease and expressed the opinion that pneumonia should now be regarded as an infectious disease, produced by a specific organism, and manifested pathologically by a lesion located principally in the lungs. He also stated that tentative experiments had recently been made by good observers which seemed to show that both lobar pneumonia and bronchopneumonia, the latter of which had heretofore been regarded as only a sequela of a previous infectious disease, as measles, influenza and the like, were in fact due to the same specific bacteria, bronchopneumonia being caused perhaps by either an attenuated form of the specific coccus or by an association with other bacteria that influenced the coccus in producing the change of local pathological action. While the discussion did not take any new or decided line of departure, it seemed

to be generally admitted that the symptomatic or expectant line of treatment was, all things considered, the best. This idea was controlled by the statement that in uncomplicated cases of lobar pneumonia occurring in children under four years of age the percentage of mortality was almost *nil*.

It did not appear to occur to any of the speakers in the discussion that as the pathology and clinical history all pointed unmistakably to a disease of infectious origin the treatment in order to be rational should undoubtedly follow the same line of thought. This is the intention of this article, and while I have only a few cases to present to demonstrate its actual value in practice, the principle of the antiseptic therapeutics here advocated must appeal to the logical and rational sense.

In papers published by me on "Carbolic Acid as an Internal Remedy," in the MEDICAL RECORD, September 12, 1896; *Therapeutic Monthly*, May, 1901; and *Pediatrics*, September 15, 1902, I have fully described the therapeutic effects of the remedy and given my experience with it, based on its antiseptic properties. The method of administration is also there given, to which I would refer my readers.

I can here only reiterate my confidence in its virtues and recommend it as the type *par excellence* of its class of remedies. This confidence has been upheld in its further use in the treatment of pneumonia, both in the bronchopneumonia and lobar pneumonia form of the disease; the former should be a better test of its therapeutic value than the latter. From numerous cases I select the following:

March 18, 1898—Tessie G., three years of age, sick four days with a severe attack of influenza; when seen, temperature 104° F., consolidation signs plainly marked at the base of right lung, general symptoms those of profound illness. Treated with cold wet compresses to the chest, changed every two hours; internally one drachm of a 2 per cent. solution of carbolic acid every two hours. Creosote and eucalyptus evaporations in the sick room.

On March 21 consolidation signs had spread to the entire right lung. Crisis came on 23d. Very little food was given during the entire illness and plenty of water was allowed as a drink. In this case there is note of a crisis, but I have since found in many cases that while carbolic acid promotes sweating and thereby probably anticipates the crisis, the actual crisis is converted into a more gradual termination or lysis.

That the remedy is harmless when used in the doses and manner I have recommended in the papers referred to, there can be no doubt. In the discussion alluded to, the writer stated that the early detection of albumin in the urine was important, as it furnished a good guide as to a favorable or unfavorable prognosis, according to the amount of albumin found. The fact that albuminuria may occur in lobar pneumonia is not a contraindication to the use of carbolic acid internally. The smoky color of the urine after taking the acid is due to a change of form into substances known as the glycuronates of hydroquinone and pyrocatechin. In bronchopneumonia there is reason to believe that by causing a curative action it naturally averts the clinical history of the disease to result in cheesy degeneration and subsequent tuberculous infection.

Attention was directed, during the before-mentioned discussion, to the great importance of keeping the digestive functions in the best condition possible by avoiding over-taxing the stomach with too much food, as the digestive functions are weakened. Dr. Winters especially drew attention to the condition of abdominal tympany, which he stated was a bad prognostic sign toward the period of crisis, owing to the embarrassment of respiration induced. This observation has been frequently confirmed by myself and others. Carbolic acid appears to control undue fermentation of the gastricc ontents, and is thus indirectly an aid in maintaining a more normal condition of digestion. This is shown by the appearance of the tongue during the administration of the remedy, as it soon becomes clean and moist where it was previously thickly coated and pasty.

In the notes of the case reported above the use of cold wet compresses to the chest is mentioned. Hydrotherapy is about the only additional treatment I now use in lobar or bronchopneumonia. Where there is a predominance of nervous symptoms, as restlessness or delirium from high temperature, in lobar pneumonia I employ sponging of the limbs and trunk with warm water at a temperature of 98° F. In bronchopneumonia I like the cold wet compress for its stimulating effect.

Occasionally when the cough is painful and annoying, preventing sleep, I give five to ten drops of paregoric about night-time.

The treatment of pneumonia in adults, based upon the theory of attacking the specific germ, appears to be gaining in favor with the medical profession. Already many reports have been published of the use of salicylates and carbonate of creosote in pneumonia, and I have treated a few cases in adults successfully with carbolic acid in full doses, twelve grains every two hours. There certainly should be no valid reason why the same disease as it occurs in children in its various forms should not be treated on the same principle, notwithstanding the opinion that the mortality rate, especially in the lobar form, is of almost insignificant percentage.

As to the value of carbolic acid as an internal antiseptic, there can no longer be any reasonable doubt. It has already proved its powers as such in infectious diseases like influenza, scarlatina, tetanus, and lastly bubonic plague. The *Lancet* for September 12, 1903, contains an article by J. M. Atkinson in which he reports in full two severe cases of bubonic plague out of many others that were successfully treated with twelve-grain doses of carbolic acid given every two hours for sixty hours and subsequently six grains every four hours for fourteen days. Further comment is unnecessary.

144 WEST EIGHTY-FIFTH STREET.

HERNIA IN YOUNG CHILDREN.*

BY W. B. DE GARMO, M.D.,
NEW YORK,
PROFESSOR SPECIAL SURGERY N. Y. POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL.

YOUR president has honored me in asking that I speak to you on hernia as a contribution to the symposium on "The Abdominal Surgery of Young Children."

The ages under consideration are from birth to the fourteenth year. Dr. Coley[1] found that, at the Hospital for the Ruptured and Crippled, one-quarter of all the cases were in children under the fourteenth year. In my own clinic for the treatment of hernia, at the Post-Graduate Hospital, the cases have not been fully tabulated, but my associate, Dr. George E. Doty, informs me that in the last 2000 cases 985 have been children under fourteen years of age, very nearly 50 per cent. A percentage between these two figures would probably more correctly represent the true proportion.

We cannot discuss this subject intelligently until we have fixed in our minds an answer to the question, why young children have hernia, and I would

*Read before the Medical Society of the County of New York, December 28, 1903.

suggest as perhaps the most important predisposing cause, defective development.

The testicle, primarily formed just below the kidney, migrates to the scrotum, where it should be by the ninth month of intrauterine life. Preceding it in its descent, is a pouch of peritoneum, which afterward becomes obliterated at its upper part and separated from the peritoneal cavity. This tubular process is known as the tunica vaginalis. The descent of the ovary in the female is identical, except that it does not normally pass outside of the abdominal wall. The similarity goes farther, however, as the pouch of peritoneum does pass down through the wall, and if unobliterated, forms the canal of Nuck, rendering the female liable to the formation of hydrocele in the inguinal canal, or the occurrence of that type of hernia designated as "congenital."

For reasons that we cannot always discover, the descent of the testicle may be retarded, or stopped altogether, at almost any point in its transit, or where this organ reaches its normal abiding place in the scrotum, the pouch of peritoneum which lies in front of, and along the cord to the abdominal cavity, may not be obliterated. It is this lack of complete development that is placed first among the causes of hernia in young children, and it is this imperfection in infancy and early life which leads to the formation of what is termed congenital hernia.

The word congenital as here used does not necessarily imply that hernia existed at birth, and is quite misleading in that respect. It refers to a defect present at birth which leads to hernia later, and allows protrusion of some of the abdominal viscera into the cavity of the tunica vaginalis (or canal of Nuck) through its unobliterated neck. This form of hernia has been demonstrated at the operating table by your speaker, in a case occurring as late as the twentieth year of life, but it rarely occurs after five or six years of age. A very common time for this type of hernia to appear is shortly after the child begins to walk.

The second most common cause of hernia in early life is believed to be constipation, the delicate tissues of the infant being unable to withstand the tension to which they are subjected by the straining of the child. Gastrointestinal disturbances with extreme distention of the intestines by gas, are also liable to damage the abdominal wall.

Following these are the commonly recognized causes of hernia, such as whooping-cough, bronchitis, crying, and tight belly-bands.

The forms of hernia met with in young children are inguinal, umbilical, ventral, and femoral; their frequency being in the order named. Femoral hernia rarely occurs in children in early life. Macready[3] found five femoral hernias in children under five years of age in 21,000 cases.

The contents of hernia in early life differ very little from the adult. Intestine is by far the most commonly protruding viscera, but omentum may at times be found. The appendix has been found present in the scrotum in quite a large number of cases. In one of my patients, it was found in a congenital sac adherent to the testicle. It was about six inches long in an infant one year old, and tapered so gradually from the normal size of an appendix to the full size of the large bowel that it was difficult to tell just where the cæcum began. It was, of course, removed before the canal was closed, and the child made a prompt recovery.

The symptoms of hernia in early life correspond in their most important features with those seen in the adult under similar conditions. The visible tumor is usually the first indication. This may, in the infant, after having been seen once, disappear for days or weeks at a time, but more commonly will be seen whenever the child strains or cries, if at no other time. The popular belief that infants outgrow hernia probably has its origin in this temporary disappearance, and this mistake is sometimes shared by the medical attendant. Such error leads to neglect, fraught with danger, and results in perpetuating an otherwise easily curable defect. In some extremely rare instances, an infant's hernia may disappear and never return; but in the greater number of cases it will increase in volume and in danger, and the golden opportunity of obtaining a cure without resort to surgery, is lost.

Pain is not commonly associated with the formation of hernia, but it is probably more frequently so with infants than adults, and it is quite certain that it causes in them far more gastrointestinal disturbance. It is no uncommon experience to see disturbances of this character, which have resisted many forms of treatment, promptly disappear as soon as an existing hernia has been properly retained.

This leads to the question as to how early in life treatment should be begun? While, it does not come within the scope of this paper, it is felt that the opportunity should not be lost of impressing upon the medical practitioner the great importance of beginning treatment at the earliest possible moment after the discovery of the hernia. By "treatment" is meant the immediate application of a suitable truss, and if this is done, surgery will seldom be needed in early infancy.

In the case of the infant in arms, it is believed that those of largest experience are agreed that very little surgery is needed, except in those extremely rare cases of strangulated hernia that cannot be reduced by gentle manipulation. Strangulated hernia that cannot be reduced at once demands the immediate services of the surgeon as a life-saving measure. Owing to the elasticity of infantile tissue, it rarely happens, that by proper manipulation under an anæsthetic, the hernia cannot be reduced. In an experience extending over a long period of years, I have had many cases of strangulated hernia in infants, but not a single instance in which I have failed to reduce the hernia. In an operative experience of 1064 cases of hernia, only four times have I felt called upon to operate on infants of less than one year old. In all of these cases strangulation had been reduced; in one three times, in another twice, but its recurrence could not be prevented by truss treatment.

The valuable researches of Dr. Dowd[2] relating to strangulated hernia in children under one year of age, have brought to light a fairly large number of these cases operated upon successfully at a very early age. Dr. Lilienthal[4] has reported a case operated on on the eighth day of life, and Dr. Erdmann[5] one on the thirteenth day. One operator has done even better than this and operated two weeks before the termination of normal intrauterine life, the child having been born at the eighth month.

That strangulated hernia is not as dangerous to the infant as to the adult is shown in a striking manner by the recent report of Dr. William Thorburn.[6] In 110 cases he had a mortality of 24½ per cent., but the ten infants in this series all recovered. Dr. Estor,[7] who has made a study of 232 cases of strangulated hernia in infancy, considers the mortality in children under two years of age much less than in the adult. He found the appendix frequently involved, and considers that it should be removed when the condition of the patient will allow. The latter remark bears out my experience as I have found the appendix protruding in several cases.

The relative importance of symptoms of strangulation in infancy are concisely, and it is believed correctly, stated by Dr. Dowd in the following order: (1) Tumor, (2) vomiting, (3) constipation, (4) difficulty in urinating, (5) restlessness and apparent pain, and (6) constitutional depression.

The probable points of constriction in a strangulated hernia in infancy are in the main limited to two, and it is hard to say which should have first place. One is at the external abdominal ring, the constriction being by the fibrous tissue which abounds in that region. The other is in one of the white, fibrous bands or rings which are repeatedly found in these sacs. Very little has been written about these white bands, which are two to three times the thickness of the other parts of the sac, and very tough and inelastic. They may appear at any part of the sac, and while they are most common in childhood, may be met with in adults. Broca of Paris refers to these bands, and speaks of their probable origin in nature's attempts to obliterate the tunica vaginalis. This would be a very acceptable view had they not been found in sacs of the acquired type. I have found as many as four in a single sac. If omentum, or intestine, is driven through one of these rings with unusual force, strangulation is quite sure to result.

In operating for the relief of strangulated hernia in infancy or early life, it is of great importance that a closure of the parts should be so made as to effect a permanent cure. It is well to remember in these cases that recovery begins from the moment the constricting band is cut, and it seldom happens that the patient is in such extreme condition that the parts cannot be closed for a cure.

This leads us to the consideration of the last part of our subject—the surgical cure of hernia in young children—that is, children under fourteen years of age.

I find that my own prejudice against operating on quite young children for the cure of hernia is becoming less every year. This is due to the apparent perfect safety of the operation, and to its complete and permanent success.

One reason why the operation has been looked upon with disfavor in the very young, is owing to the difficulty of maintaining the parts in an aseptic condition during the process of healing. Personally, I have had no trouble in this regard since I adopted the uniform practice of sealing the wound with collodion, which forms a perfect protection. Nor have I found it necessary to put the infant in a plaster cast as advocated by several operators. When the wound is hermetically sealed, there is no objection to the frequent changing of the dressings should they become soiled. Usually there is not sufficient soiling to make this change necessary for the first four or five days.

Why not, then, operate upon all young children? The answer to this is, that 90 per cent. of children under three years of age can be cured by mechanical means, and proper care, and it is only right to give the parent the option as to how the child shall be treated. This, when the truth is stated to them, usually results in the avoidance of the operation. After the child passes its sixth or seventh year of age, the statement to the parent must be different, as we know that after that age the child is very rarely cured without an operation.

My own operative experience is that in 1064 cases 179 were children under fourteen years of age, and without a single recurrence or death resulting from the operation. There is, perhaps, nothing in surgery more satisfactory than the operative cure of these cases.

The method used cannot be entered into here farther than to state that it was essentially that of Bassini, using, however, kangaroo tendon as a suture material in place of silk. The greater part of these cases were up on the tenth day, and out of doors by the fourteenth. Primary union has been the rule, and deep-seated infection has not been seen in any case.

The indications for operating on hernia in early life may be tabulated as follows:

1. Strangulated hernia—immediate operation.
2. All cases not controlled by truss.
3. Occasional protrusion with threatened strangulation.
4. When truss-wearing causes pain.
5. On children that cannot be brought regularly for attention.
6. In all cases of femoral hernias.
7. On all children over seven years of age.

RADIOTHERAPY, WITH REPORT OF CASES.*

BY D. C. DENNETT, M.D.,
WINCHESTER, MASS.

THE advance of medicine in the last ten years has been like the advance of surgery under Listerism. Surgery had its innings first and now medicine is taking its turn. And so rapidly does one brilliant play in the field of medical discovery follow another that the spectators in the scientific as well as in the lay world, stand amazed. With bated breath we watch, feeling that even more brilliant things are about to be witnessed. It seems as though the guiding star of medicine had suddenly caught the eyes of all scientists, that the chemist as well as the bacteriologist and electrician were vying with each other in the tribute offered at the throne of Æsculapius. Certainly the recent discoveries of scientists working in other than medical fields bid fair to be of the utmost use in the treatment of certain diseases of man, even if they do not entirely displace old methods and establish a new system more radical and more potent. The discovery of the *x*-rays in 1895 by Prof. W. C. Röntgen of Wurtsburg, the discovery in 1899 of radium by Professor and Madame Pierre Curie of Paris, together with the discovery that the ultraviolet and some other rays have more or less curative power over certain diseases, has already resulted in a new system of treatment which we call radiotherapy. The term radiotherapy is no longer applied to the treatment of diseases by the *x*-rays alone. So we have placed in our hands a new weapon of yet unknown power with which to combat disease. Let us examine it and test it. No adequate idea of its power can be gained without using it and reporting correctly the results after its skilful application in many cases. For the next few years it will be well to keep a record of all cases, reporting all facts and all phenomena. Having begun the ray treatment before radium was discovered, and when the term radiotherapy was applied to the treatment of diseases by the *x*-rays only, my experience may possibly justify me in reporting the following cases:

CASE I.—Mr. S., sixty-six years old, native of New England, a maker of piano keys; consulted me February 10, 1901. He stated that he had suffered

*Read before the Middlesex East Division of the Massachusetts Medical Society.

greatly from eczema for more than seventeen years. The disease began in the scalp, to which place it was confined for some months, subsequently involving the lower limbs and back. The greatest annoyance from it was at night, the itching keeping him awake. The patient stated that he did not expect to be cured, having suffered so many years, and having been treated by many physicians, but would I please give him something to stop the burning and itching of his disease that he might sleep. He had been through the whole list of washes and ointments, with at best but temporary relief. Examination revealed a large patch of red, infiltrated, thickened eczema, the worse for scratching, below the right knee, another area on the inner aspect of the left thigh, one on the buttock, and one in the lumbar region of the back. There was no eczema of the scalp at this time. *X*-ray treatment was begun at once. An exposure of eight minutes was made, the tube distance being three inches for seven minutes and one inch for one minute.

On February 14 the patient returned and stated that the itching had been less since the first treatment. Another treatment of eight minutes with the tube one inch away was given. February 17 patient stated that the itching had stopped and that he felt only a slight burning sensation. On February 21 the fourth treatment was given. Marked improvement was noticed in the appearance of the disease and all itching and burning had stopped. At the end of fourteen treatments, given at intervals of three to four days, the patient was discharged cured. Patient was examined Friday, October 2, 1903, two years and six months from the time he was cured, and he stated that there had been no return of the disease. In place of the thickened, inflamed patches there was soft, normal skin. In this case a close exposure was given for about one minute of each treatment, the balance of the treatment being at a distance of three to four inches. No dermatitis was produced, and no new symptoms noted.

Case II.—Mr. H. C. B., sixty years of age, native of this country; lumber dealer, a strong man of good general health, consulted me November 15, 1902, for eczema of the hands. He stated that he had suffered a great deal with the disease of his hands for over two years. He had used various ointments and washes without much relief. An *x*-ray treatment was given of about eight minutes duration, the tube distance three inches. The second treatment was given November 17. No change observed at this time. November 20 the third treatment, November 22 the fourth. At this time improvement was noted. The patches were thinner, less inflamed, and the itching less. November 25 a three minutes' treatment was given at a distance of six inches, the fingers of both hands showing an *x*-ray dermatitis accompanied by considerable burning. The usual treatment for a burn was given, and the patient instructed to return at the end of a week. December 2 another treatment was given and marked improvement in the disease noted. The dermatitis had subsided. December 5 the seventh treatment was given, and on December 10 the eighth and last. On this date the patient was discharged cured. I examined this patient October 3, 1903, ten months after cure, and there had not been the slightest return of the disease. The hands were smooth and soft.

Case III.—Mr. B. H. R., fifty-one years old, keeper of a restaurant; general health good. This was a case of chronic eczema of the buttock, inner side of the thigh and perineum. The patient told me that he had suffered with the disease for twenty years, during which time he had used one nostrum after another. The itching was worse at night after he had retired and kept him awake a certain portion of each night. Began treatment with the *x*-ray May 17, and gave a daily treatment until an *x*-ray dermatitis was produced. Treated the dermatitis for a week then resumed the rays, giving in all eleven treatments, at the end of which time patient was discharged cured. Patient was seen October 3, 1903, six months after the last treatment, and there had been not the slightest return of the disease.

Case IV.—Capt. W., fifty-eight years old, lumber dealer. He served in the Navy during the Civil War, and was broken in health by a severe attack of yellow fever. He was not well for some years after this. General health good at this time. This patient came to me July 24 to be treated for severe fissure eczema of the hands, with which he has suffered for two years. There was much thickening and infiltration of the tissues, with cracks in the palms which were very sore and which frequently bled. His hands were so stiff he was unable to close his fingers, which were about half extended. Daily treatments were given with the *x*-ray until a slight dermatitis was produced, the tube distance being from one to two inches, and the treatment lasting from five to eight minutes each. After sixteen treatments the patient was discharged cured. During the course of this treatment the tactile sense in the fingers became much diminished and numbness was complained of. The new skin which formed was soft and smooth.

Case V.—Mrs. H., widow, a little over fifty years of age. Eczema of external ear and external auditory canal. Began treatment June 30, 1902. Was discharged cured after nine treatments. In the fall of 1902 there was a slight recurrence of the disease which appeared cured after four more applications of the rays. I saw this patient Monday, October 5, 1903, and there was a recurrence of the disease in a small area and mild form. This patient received in all thirteen treatments, not strong enough at any time to produce dermatitis. She was advised to return for further treatment, in which event the ray will be used until a slight dermatitis is observed.

Case VI.—Miss R., twenty years of age, student in a nurse's training school. Eczema of the external ear. Seven treatments with the *x*-ray. Discharged cured. No dermatitis was produced, yet the hair came out, leaving a bare scalp of an area of about one and a half by three inches above and behind each ear. A new growth of hair has since developed. This case was treated last July, and was of two years' standing. October 3, I was informed by the patient's sister that there was a slight recurrence of the disease.

Case VII.—Mrs. B., aged thirty years, married, no children, once pregnant and delivered of a still-born child at term. Psoriasis since she was twelve years of age. Since that time she has never been free from the disease except during the period of gestation when it entirely disappeared, recurring after childbirth. After nine treatments the disease disappeared from the outer aspects of the forearm and forehead, which were the parts involved.

Case VIII.—Mr. S., sixty two-years old. Epithelioma of the lower lip, first noticed one year ago. Patient was referred to me for treatment December 31, 1902, presenting a sloughing tumor of the lip, which had not been benefited by the paste treatment. He suffered great pain and was unable to sleep nights from that cause. After twenty-two treatments, during which the patient was three times slightly burned by the rays, the tumor had disappeared save for an indurated mass about the size of a kernel of corn that looked like scar tissue and which took the

place of the slough. This was removed with the knife. The patient's beard, from his lip to his chin, was removed by the *x*-ray, and at this writing, eight months since the patient was treated, it has not grown again. I saw the patient Monday, October 5. There were no signs of recurrence of the disease.

CASE IX.—Mrs. W., fifty-four years old, malignant disease of the stomach. This patient's grandfather on her mother's side died of cancer and her mother's sister died of the same disease. On her father's side an uncle and an aunt died of cancer. The disease developed very rapidly in the spring of 1903, and soon after I discovered the tumor the *x*-ray was applied. Daily treatment of from eight to twelve minutes was given with a coil at the patient's home. A very marked pigmentation of the epigastric region resulted, but no dermatitis was produced, although the treatment was the most vigorous of any I have ever given. The pain which the patient suffered before the ray treatment was begun, and which made necessary frequent doses of morphine, gradually disappeared until no morphine was required. The foul odor of the disease was also greatly lessened. No other benefit resulted. The patient sank rapidly and died late in May. The insusceptibility of some patients to *x*-ray dermatitis was well illustrated in this case. I have produced dermatitis in many cases with one-quarter as much exposure.

CASE X.—Mrs. K., aged sixty-five years. Epithelioma of left forearm. The patient's father had cancer of the lip. Mrs. K. stated that her tumor began to develop six months before she applied to me for treatment. It started from "a small pink spot" that had existed some months, at least, before it began to cause trouble by further development. *X*-ray treatment was begun the middle of September, and after sixteen treatments the patient was discharged cured October 19. After ten treatments the necrotic center of the tumor came away, leaving a red, granulating base, which healed rapidly.

CASE XI.—Miss M., fifty-four years old. Rodent ulcer of left cheek, extending up the side of the nose to the inner canthus of the eye and involving the inner half of the lower eyelid. Growth started from a little red spot that had existed on the cheek below the eye for some years. Period of present activity five months. Patient now under treatment. Twelve applications of the *x*-rays have been made. The appearance of the disease has entirely changed. A granulating center now presents itself; the swelling and induration of the surrounding tissues has been greatly reduced.

CASE XII.—Mr. T., seventy years of age. Beginning malignant disease of the right side of the nose near the eyelid. Patient was referred to me for *x*-ray treatment by a surgeon on the staff of a Boston hospital, at which hospital patient's left eye and part of the orbit was removed on account of malignant disease which began just below the eye and extended upward. Operation one year ago. Reappearance of disease on right side first noticed some three months ago. Began treatment in September. Patient discharged cured October 31.

Time forbids the detailed report of more cases. I have reported only those the course of which I have been able to follow from the time of treatment to the present date. They are a few of many which I have treated in the last three years, and are a fair sample of the general run of cases. Eczema, according to my experience, will melt away before the *x*-ray like snow before an April sun. Certain malignant diseases of the skin will yield to it in a large percentage of cases. The pain and odor of cancer are stopped in a large percentage of cases and relieved in some degree in nearly all. Some cases of phthisis have been reported cured by it. I have treated several cases in which the cough has been greatly benefited and improvement in all the symptoms noted—cases in which the disease has been rendered apparently non-progressive. I have had no cures thus far. In the field of ophthalmology the *x*-ray has taken a conspicuous place in some quarters. Trachoma seems to yield readily to it, many cases of granular lids have been cured, and in some instances ulcers of the cornea have been stimulated to rapid healing. Some other diseases appear to have been cured and still others benefited. The range of its usefulness, and its exact indication is yet to be determined. In my own practice the *x*-ray has proved to be the most powerful and useful in treating, first, eczema and psoriasis; second, superficial malignant diseases; third, pain of deep cancer. neuralgia, cough of phthisis, muscle pains, and ulcers. It seems to me that the *x*-ray has the right power but not enough of it. That is, if it had more of the same kind of power I think it would cure deep malignant disease. Radium appears to have a greater power of the same, or a very similar kind, and I believe it has a great future. It may yet supersede both the *x*-ray and the violet ray in the treatment of disease.

The *x*-rays, as well as the radium rays, are fatal to certain living organism. It causes irritation of the skin, and in large doses destruction and sloughing of the skin and deeper tissues. It is said to dilate the cutaneous blood-vessels, but it has seemed to me that in some cases the dilatation was preceded by a vasomotor spasm and blanching of the parts nearest the tube. It is said to produce a local increase in the number of leucocytes in the blood, and in cold-blooded animals to inhibit the heart. It will cure without producing necrosis—that is, it is not necessary to produce necrosis to cure—the cure is not the result of necrosis. No exposure strong enough to produce more than a slight dermatitis should ever be made, and rarely should a dermatitis be produced at all. If we go much beyond a dermatitis we not only impair the vitality of the tissues exposed but do a constitutional harm, besides making the parts more vulnerable to disease at some future time. It seems to me that the power of the *x*-ray to cure germ diseases depends upon the destruction, directly or indirectly, of certain living organisms or germs. Its power to relieve deep-seated pain, has been attributed to the superficial vasomotor dilatation which it causes. With this opinion I do not agree. I believe the pain is relieved by direct action on the nerve terminals and possibly the deeper nervous centers. I have stopped pain with the *x*-ray in cases in which superficial vasomotor dilatation produced by other means did not stop it. The various rays exert an influence upon vegetable life as well as upon animal life. Plants are stimulated and even destroyed by exposure to some of the rays.

The proper dose of the *x*-ray varies, like the dose of any remedy, within pretty wide limits. Its proper administration can only come through experience, and there are several important factors determining the length of time it is proper to expose a patient to its influence. In the first place we should bear in mind that there are certain forces excited by the rays that continue in operation a considerable length of time after the application of the rays has ceased. A burn may not show itself for days or even weeks after the parts have been exposed to the tube. A patch of eczema or an epithelioma will sometimes disappear after two or three treatments when, at the last treatment, no change was noticea-

ble in the superficial appearance of the disease. After a certain number of daily treatments have been given it is well to discontinue them for a week or ten days and note if progressive improvement does not take place. The treatment should not be carried too far lest a permanent impairment of the vitality of the tissues result, and a predisposition be established to the development of some of the very diseases we seek to cure with it. Atrophy and cancer have followed over-exposure to the rays, and ulcers of the most intractable type have been caused. I am satisfied that many unnecessary treatments are given, and that exposures are often improperly timed. In order to make a proper exposure it is necessary to know three things: First, the power of the machine that excites the tube; second, the power of the tube, and, third, the patient's susceptibility to the action of the rays. Tubes vary in penetration and power within pretty wide limits. A five minutes' exposure with a given tube may be equal to a ten minutes' exposure with another tube. So, without knowing the penetration of a tube, no exact directions can be given concerning the proper length of the exposure. The varying results from the use of the *x*-ray by different operators must be accounted for by the varying qualities of the tubes used and a difference in method of application. Some patients are more susceptible to the action of the rays than others. Fair, delicate, thin-skinned types require a smaller dose, as a rule, than stronger patients of the brunette type. We do not know the ultimate results of too prolonged treatment. It may be that, by impairment of the vitality of the tissues, it will favor the development, fifteen or twenty years later, of senile gangrene, some neurosis or other disease. This is true, also, of the violet ray and the radium ray. The action of the violet ray seems to be similar to that of the *x*-ray, and it appears to be useful in the same class of diseases. Some cases have been reported cured by it that the *x*-ray failed to cure. Some cases have been reported greatly benefited by the radium rays that did not respond to either the violet or the *x*-ray. Radium is said to produce three rays, one of which is far more penetrating than the *x*-ray, and one of which seems to be similar to or identical with it. The Crookes tube may be excited by a coil or static machine. In my office I use both. My static is a powerful ten-plate machine and I prefer it to the coil. It seems to me that the ray generated by it is more efficient and less liable to cause dermatitis. Some think that the coil is better for skiagraphy. A ten or twelve-plate static machine (I would not advise a smaller one) with a tube properly adjusted to it certainly does very satisfactory work, and is sufficient for all therapeutic purposes. The selection of a tube to fit the machine is an important matter. The vacuum must not be too high or too low, but carefully made to fit the particular machine to which it is to be connected. Bedside treatment must be given with a coil, and here it has a distinct advantage over the static machine. Another advantage is its lesser bulk and cost.

The Doctor and the Law.—In the writings of Hammurabi of Babylon, 2250 B.C., the following interesting laws are found: "If a physician operates on a man for a severe wound with a bronze lancet and saves the man's life, or if he opens an abscess (in the eye) of a man with a bronze lancet and saves that man's eye, he shall receive ten shekels of silver (as his fee). . . . If a physician operates on a man for a severe wound with a bronze lancet and causes the man's death, or opens an abscess (in the eye) of a man with a bronze lancet and destroys the man's eye, they shall cut off his fingers."

Diastolic Aortic Murmurs without Valvular Lesions.—G. A. Gibson believes with Babcock that there is a form of aortic insufficiency, which although not due to valvular defect, yet presents the same clinical features as the organic form, and is so frequently encountered that it may here be briefly dwelt upon. This is a relative incompetence of the semilunar valve, and its causes are found in conditions that predispose to stretching of the ventricular wall and of the basal ring of the aorta. The writer cites two cases in point. The first patient was a man aged thirty years. He was suffering from chronic nephritis. In the aortic area, a hard systolic murmur was heard, which was propagated into the carotids. The second sound was impure and was followed by a soft blowing diastolic murmur, best heard over the sternum, and hardly propagated at all. Autopsy revealed a dense band surrounding the aorta and pulmonary artery. This caused considerable displacement as well as constriction. The writer believes that the diastolic murmur was produced, not by stretching of the orifice (which was negatived by the result of the post-mortem examination), but by faulty adaptation of the aortic cusps. The systolic murmur was no doubt largely due to some dilatation of the vessel beyond the constriction. The second patient died of aneurysm of the aorta. About a year before his death a diastolic murmur developed over the upper part of the sternum. In neither case was there any permanent stretching of the orifice. The writer believes that the murmur was due to faulty adaptation of the different cusps of the aortic valve. It is impossible to conceive of temporary dilatation, and in default of any pathological proof of enlargement of the orifice, faulty application of the individual cusps to each other can alone be entertained as the cause of regurgitation.—*Edinburgh Medical Journal.*

Elephantiasis and Its Treatment.—William Elde reports this case. The condition which was considered elephantiasis had been noticed for fourteen or fifteen years. The patient had twice resided in Burmah. The last residence there had been seventeen or eighteen years ago. During her stay in India she had two attacks of "fever," and she suffered much from the bites of mosquitos. She did not notice the swelling in the limb till a few years after her return. During the early months and years of her illness she suffered much from feverish attacks, which at the time were believed to be influenza. These attacks occurred so often, however that they were a little puzzling. They recurred sometimes at intervals of a month, and again a few months would sometimes pass without an attack. The attacks were far more frequent in the summer than in the winter. In later years the attacks became less frequent, but the limbs had gradually become more swollen. The patient was very uncomfortable in a hot atmosphere. She has a very distinct dislike of fish. Treatment was begun in March and continued till June. The patient was put to bed and given a light ordinary or convalescent diet. She was daily massaged, special attention being paid to the swollen limb. At first massage was given for a short time. Later it was prolonged. The constant current was also applied daily to the swollen limb, the poles being applied over the most swollen parts. The limb was also put into an electric heat bath daily. General tonics were given internally, and medicinal treatment was varied as the patient's digestive symptoms required. After the massage was discontinued, an elastic stocking was ordered. The limb which diminished to about the size of the normal one, has remained in practically the same condition since. No filaria could be found in the blood, but there was an increase of lymphocytes and a percentage increase of polymorphonuclear eosinophiles. There was not much anæmia. The patient's digestive troubles were treated by washing out the stomach.—*Edinburgh Medical Journal.*

THE TREATMENT OF TYPHOID FEVER.

In the treatment of typhoid fever, in which every general practitioner is interested, there is always something to be learned either by suggestions of new methods or by corroborations of old and generally accepted lines of procedure. From such points of view the subject is never an old one and its discussion is always fraught with practical benefits to patient and physician.

In an exhaustive symposium on enteric or typhoid fever in the January issue of the London *Practitioner* appear three chapters on the topic in question: One by Sir John W. Moore, M.D., physician to the Meath Hospital and County Dublin Infirmary, one by Dr. Herbert P. Hawkins, physician to St. Thomas Hospital, and one by Dr. Thomas McCrae, Associate on Medicine in the Johns Hopkins Hospital. These gentlemen, although following parallel lines, present respectively the British and American methods of dealing with the disease. As might be expected, there is a marked unanimity of opinion regarding the fundamental principles upon which the therapeutics of the malady should be based. This fact is comforting at the start, as much confusion as to general indications is thus avoided, giving corresponding force and directness to the conclusions arrived at.

When we admit that the foundation of all rational treatment of typhoid fever rests upon the fact that the pyrexia itself is not the main object for attack, but is, so to speak, a beneficial reaction against the fever poison, we can better understand the inutility of mere antipyretics to fulfil their supposed indications. We by the latter means reverse conditions by striving to screw down the safety valve rather than give it a proper vent for the force behind.

There being no typhoid serum to counteract purely toxic effects, reliance must be placed on mitigating the latter with the least possible danger of interfering with the conservative metabolic processes. Hence cold bathing is considered the most safe and certain means of controlling or reducing the high bodily temperature. Under certain circumstances, however, Sir John W. Moore admits that the ordinary coal-tar products so commonly used may be of incidental benefit when administered in small or moderate doses to meet special and minor indications. Thus "they assuage the toxæmic rheumatoid pains of the disease and so allay cerebral excitement and invite sleep, . . . but pushed so as to reduce temperature, they imperil life." Dr. Hawkins is substantially of the same view. "There may be cases and conditions in which an occasional dose of quinine, phenacetin, antipyrin, or salicylate of soda may be used. But the attempt to control pyrexia throughout a long illness has nothing to recommend it. Such a method is usually inefficient, and if it is to have a substantial effect it must be carried out on a scale that is not free from danger." Hence he agrees that to the proper end "there is nothing like cold water." The reason for the latter treatment is based on conditions that obtain in high fever: "The continuance of a body temperature averaging 103° F. for three, four, or more weeks is a definite tendency to death which can be greatly diminished. It is probable that much of the injurious effect, especially on nerve tissue and cardiac muscle, which was formerly regarded as due to pyrexia alone, should more correctly be ascribed to toxæmia. But we may safely believe that with a lower average daily temperature the greater will be the conservation of the tissue resistance to bacterial life and activity."

In the Johns Hopkins Hospital antipyretic drugs as such are never used. According to Dr. McCrae, "hydrotherapy enters into practically every method of treatment of typhoid." As to drugs, "Many of the patients get no medicine at all. None of the so-called intestinal antiseptics are given. If the heart becomes rapid, the pulse weak, and the first sound indefinite, strychnine is given in doses of $\frac{1}{60}$ to $\frac{1}{30}$ grain every four hours with excellent results. This usually is not given continuously for more than twenty-four hours. For the severe headache, small doses of bromide and codeia or of opium are sometimes given."

The routine administration of alcohol is objected to. The rate and strength of the pulse are the only guides for its use. Thus at the height of disease, when the heart is clearly failing and the nervous disturbances are profound, from three to ten ounces of whiskey or brandy may be given. It is specially indicated in old persons from the first.

The various forms of water treatment are thus advocated in their order of importance: (1) Immersion in cold baths (70°–50° F.). (2) Tepid sponging (3) The wet pack (60° F.).

McCrae, with Brand, advocates tubbing from the beginning as a standard treatment, giving as his reason that it lessens the likelihood of severe manifestations late in the attack. This, however, must be admitted as a negative proof of its value, as it is difficult to be sure of what may not happen. As the nervous symptoms are to a great extent an index of the degree of toxæmia, and as these phenomena become less pronounced with the bath system, he quite logically concludes that tubbing increases the elimination of toxins. Thus the main object of the baths is not to decrease temperature *per se*, as during the height of the attack they have no appreciable effect in such a direction. The immediate effects are on the circulatory and respiratory systems. The pulse becomes reduced and firmer, the breathing is stimulated, congestion dissipated, and existing bronchitis benefited. By its tonic effect on the skin there is less liability to bed-sores. The main purpose is, after all, the reduction of mortality, from five to seven patients being saved in every hundred suffering from pure toxæmia.

At the Johns Hopkins, patients are tubbed every three hours when the temperature is 102.5° F. and over. This temperature, it must be confessed,

would not be considered as sufficiently high by the ordinary practitioner to warrant such seemingly radical treatment, but in keeping with the indications of tubbing as previously given, the course is consistent enough. The first tub is usually given at 85° F. and succeeding ones 5° lower until the most suitable point is reached. The time occupied for each bath is usually from ten to fifteen minutes. Should the patient be delirious, the first bath can be given at 70°. During immersion the surface of the body is rubbed constantly. Shivering is a common but insignificant sign. Patients are removed immediately from the tub if there be great distress, unusual cyanosis, vomiting, hemorrhage, abdominal pain, or symptoms of collapse.

As to the general objections against immersion, Dr. McCrae urges that they are due to faulty methods; that every one superintending a clinic should experience an immersion himself—an excellent general principle that would eliminate any unnecessary harshness and ill-consideration in any other methods of treating disease.

It is generally agreed that typhoid-fever patients should be sparsely fed. The condition of the gastrointestinal mucosa gives ample reason for this. Milk is the article preferred. Albumen water can be used as an alternative, also buttermilk, boiled milk, koumys, or whey. As a rule an adult should take four ounces of milk every four hours. Ice cream may be taken at any time.

Beef tea, peptonoids, and similar preparations are never given in Johns Hopkins, but if a change of diet is required it is usually accomplished by cutting off the milk and giving only whey and albumen.

The value of simple diet is abundantly proved in the absence of gastrointestinal disturbances. The argument against too much meddling with constipation has a like basis. "If possible leave the bowels alone." "We prefer a state of constipation, which is the rule in a majority of our patients. If necessary, the bowels are moved every second day by a simple enema, preceded sometimes by a large injection of oil. No purgative is given by mouth during the attack." On the other hand, if diarrhœa appears it is merely a signal for the reduction of the diet. If not, bismuth or opium may be indicated. For tympanites, turpentine externally or internally is recommended.

"With the question of food," says Dr. McCrae, "goes an equally important one, viz., the amount of water." Certainly too much emphasis cannot be laid on this very essential requirement. To the old-fashioned practitioner who believed water to be absolutely harmful in fevers this sounds like the rankest heresy; but too much stress cannot be laid upon the need of a newer doctrine.

We cannot give a better practical turn to the general therapeutics of typhoid fever, or in fact any other form of fever, than to quote in full what Dr. McCrae says on this subject:

"The need of giving to patients large amounts of water is too often forgotten. Constant emphasis is laid on this, and a minimum of three litres of fluid (two and one-half quarts) *per diem* is the rule in this clinic. The endeavor is always made to give larger amounts. Many patients take six or seven litres a day (five to six quarts). The delirious patients are pressed to take it every hour at least. Those who are rational have a supply constantly at the bedside which they are encouraged to drink in addition to the regular feedings. To make sure that a typhoid-fever patient is getting enough water requires constant effort on the part of the physician and nurse. The amount of urine passed is a very valuable guide. We consider that too much importance cannot be given to this. Probably typhoid-fever patients suffer more from lack of water than from any other thing. 'More water' might well be the motto inscribed in all our typhoid-fever wards. Do not let us forget that our patients will do perfectly well on water alone for some days."

THE RELATIVE IMPORTANCE TO THE COMMUNITY OF PNEUMONIA AND TUBERCULOSIS.

Dr. ARNOLD C. KLEBS of Chicago read a paper on the above subject before the Chicago Medical Society. He drew attention to the fact that mortality statistics are by no means to be implicitly relied upon, and that, especially in this country, the prevalent classification of diseases is thoroughly unsatisfactory, and gives possibility for error. Figures quoted, however, by Dr. Klebs go to show that pneumonia is not so deadly a disease as is generally imagined, and that so far as prognosis is concerned, tuberculosis is far more dangerous to life and health than is pneumonia. With regard to the comparative infectiousness of the two complaints, the author said that "In the light of modern research there can be no doubt of their communicability under certain conditions. For tuberculosis at least this has been proved without a doubt. For pneumonia we have in this respect only indirect evidence, since its bacterial etiology is by no means yet clear. The observation of several pneumonia epidemics, the spread of the disease through a house, and other factors speak for its communicability. The whole course of the disease speaks for its infectious character, and still we are lacking definite information as to its mode of communication."

Dr. Klebs is strongly of the opinion that a wise and energetic action against the excessive use of alcohol will probably have a marked bearing on the mortality from pneumonia—much more so than general hygienic measures, which, so far as our present knowledge goes, have only an indirect influence on the mortality of the disease; and he further makes this important statement: "The very fact of a increasing mortality from pneumonia in late years when general hygienic conditions have steadily improved, would disprove the efficiency of such course of prophylaxis."

Dr. Klebs sums up as follows: (1) That the relative economic importance of pneumonia cannot be estimated by a mere comparison of total mortality figures for each disease. (2) That the apparently high mortality figure, and its increase of late, for pneumonia, is produced by the enormous death rate, and its increase attributed to this disease in early childhood. (3) That, therefore, the high mortality from pneumonia, and to a certain extent its increase, is due to a classification of different ill-defined pathologic conditions under one name while that from tuberculosis represents that of a well-defined morbid entity. (4) That for this reason and on account of the relative shortness of disability

sickness and frequent recovery in pneumonia, the great length of disabling sickness and infrequent recovery in tuberculosis, the relative importance of the two diseases is so vastly different, that a comparison on economic grounds reveals the overpowering danger from tuberculosis. (5) That the steady decrease of the tuberculosis death rate can be explained on the grounds of increasing improvement of hygienic conditions in late years and as the result of specific prophylactic measures. (6) That the increase of the pneumonia death-rate occurring in a time of improving hygienic and sanitary conditions and of a general application of antiseptic principles, shows its independence of these features. (7) That therefore, and in view of the still enormous mortality from tuberculosis, its demonstrated preventability and the possibility of its arrest only in its earliest stages, the institution of educational measures in regard to personal and public hygiene widely and specifically applied, for the prevention of this disease, seems to be distinctly indicated. (8) That since pneumonia is a multiple disease as pointed out by Wells, "the fundamental information on which prophylactic rules may be formulated is not yet at hand." The subject, in fact, needs further investigation from a bacteriologic and epidemiologic standpoint before "exaggerated and irrational notions in regard to its dangers and its avoidance" are communicated to the public by advisory official bodies.

There is little need of argument to show that tuberculosis is a far greater menace to the community than is pneumonia. The comments of Dr. Klebs on the comparative infectiousness of the two diseases are very much to the point. Pneumonia is doubtless communicable under certain conditions, but the evidence in support of its general infectiousness is inconclusive, and there should certainly be further investigations before a definite statement is made. Pneumonia is more common in this country than in Europe, one reason for this probably being that the houses and offices are heated at too high a temperature, rendering those who occupy them susceptible to cold. Another reason, at any rate, for the prevalence of pneumonia in New York, at least, is the changeableness of the weather, and perhaps to some extent during the past few weeks, the inadequate and eccentric manner in which the elevated and street cars have been heated. Pneumonia will attack those whose vital forces are at a low ebb; hence the large mortality from the disease among the old and very young, and among those who are addicted to the excessive use of alcohol.

Renal Opotherapy in Albuminuria.

Kidney affections are perhaps more discussed, and more methods of treating them are suggested and practised than is the case in any other disease. The Paris correspondent of the London *Lancet* sends a letter to its issue of January 2, in which he refers at some length to what he terms a sensational communication made by Professor Renaut of Lyons, at the meeting of the French Academy of Medicine held on December 22 last. The professor stated that investigations made by him afforded good grounds for thinking that many cases of albuminuria will in future be curable. "The following," says the *Lancet* correspondent, "are the conclusions which Professor Renaut has drawn from his researches. Extract of macerated kidney administered to patient's suffering from renal insufficiency is one of the most active and most efficacious methods of medication hitherto employed. It restores the function of a waterlogged kidney more than does any other known means. It acts both quickly and surely even in cases in which no preliminary depletion of the kidney, as by the application of leeches to the triangle of J. L. Petit, has been tried. The extract has a powerful diuretic action, and when employed for a reasonable space of time it brings up the urinary output to the normal and maintains it at that level. Further it has no harmful influence upon the affected kidney. Among other advantages of this method of treatment is that it rapidly reduces the output of albumin by the kidney, owing to its renewing the activity of the gland. It will even cause a disappearance of the albumin for a long period, and so there is every chance that, the tubules of the kidney being given functional rest, the renal epithelium will be renewed, at least in those cases in which such renewal is histologically possible. It is therefore, as Raphael Dubois discovered and demonstrated, at one stroke, an antitoxic method of the first class. The antitoxin consists of the 'preproducts' of the glandular secretion of the epithelial cells of the convoluted tubules, the important point ascertained by Dubois being that this antitoxim is not destroyed by the gastric juice. It is this fact which allows of the application of renal opotherapy. The kidney extract introduced into the organism per os exercises a real antitoxic effect."

The only injurious effects observed from this manner of treatment were that there were slight symptoms of poisoning, giving rise to certain skin eruptions, or after the extract had been administered for a few days, slight gastric disturbances occurred. This treatment should be begun at as early a stage of the disease as possible, and it should not be substituted for other therapeutic measures, but used as an adjunct to them.

Poisoners of the Sixteenth and Seventeenth Centuries.

Two works have been recently published in France relating to poisonings. "Poisons et Sortilèges," by Drs. Cabanès and L. Naas and "La Sorcelleric et la Science des Poisons au 20e Siècle." The New York *Evening Post*, January 9, has an article from its Paris correspondent in which these volumes are reviewed, and a sketch is given of the history of the science of poisoning and of poisoners. Poisoning as a science had its inception in Italy. The most famous of the Italian poisoners was René, the perfumer of Catherine de Médicis. René Bianco accompanied the Queen to France, when Catherine de Médicis married Henry II. Another Italian poisoner was a member of Catherine's suite. "The chapters written by Dr. Cabanès on the use of poisons in the sixteenth century," says the writer in the *Evening Post*, "are very interesting, and he is able to correct many historical errors. He gives many details regarding the poisons employed at that time. The famous surgeon Ambroise Paré writes with much caution on the subject: "If I had my will, no man would ever have written on the subject of poisons, so that we should have to defend ourselves only against beasts, which is easier than to defend ourselves against the wickedness of traitors and poisoners." . . . We possess many documents on the history of criminality in the seventeenth century. Trials were frequent in which sorcery was really a cover for poisoning, and not a few of the sorcerers tried were in reality mere

poisoners. In 1679 the King created the "Chambre ardente," which had at once to judge three hundred and thirty-seven people suspected of being poisoners, and many were condemned to suffer capital punishment. From that date we hear no more of sorcerers, and trials for sorcery became exceedingly rare. On the other hand, trials for poisoning became more common.

M. Masson writes of the medical account of Richlieu up to the time of his death, contained in a series of despatches from Louis XIII. It was feared that poison might be administered to Richlieu, but he eventually died from pleuropneumonia. Marie de Médicis, the mother of Louis XIII, is another subject studied from its medical aspects by Dr. Masson, and he concludes that, like three-quarters of her family, she died a violent death, presumably from the effects of poison.

Drs. Cabanès and Naas treat of the reign of Louis XIV. The attempts at different times to poison Mazarin, Foquet, Colbert, Louvois, and De Lionne are referred to; the mysterious death of madame; the death of Marie Louise of Spain; the criminal projects of Madame de Montespan; and of the famous poisoners, Voison and Brinvilliers, are likewise made the subject of comment, as are also the poisoning and suspected poisoning of various other persons of high degree.

In the times of which the authors speak, poisoning was not only a frequent and popular means of ridding oneself of one's enemies, but was also an art, to attain proficiency in which much study and ability was needed. The use of secret poisons was then known, the knowledge of which has been lost, or at any rate can be but a matter of supposition.

Medieval Hospitals.

The *Dublin Review*, in a recent issue, contains a fascinating account of hospitals in the Middle Ages by Elizabeth Spearman. The rise and development of these institutions is traced in an illustrative manner, and the architecture, methods of arrangement, management and care of patients is adequately sketched. "The name 'hospital'," itself remarks the writer, "in its special application coming to us from the Middle Ages, indicates the period in which these institutions took their rise. In the times of the Greek and Romans, or of any of the old eastern civilizations, there was no very great development of poor and sick relief. When, however, Constantine became ruler of the Roman Empire and Christians received official recognition, charitable foundations sprang up on every side, homes for the aged, orphan asylums, hostelries for pilgrims and wayfarers, and hospitals proper for the sick and infirm. It must be understood that all these arose as a result of ecclesiastical influence, and were established on a religious basis. The church in those days exerted a potent sway, and in many ways used her power mercifully and to the good of mankind. The feudal lords, strong-handed, but ignorant and superstitious, lived in wholesome dread of the harm which might happen to them in this world and in a future life if they neglected to obey the behests of their spiritual advisers. Thus they gave to charity with a lavish hand, impelled to do so rather by fear than by Christian love. There is little need to say that the science of medicine in those days was not very far advanced, and beyond bleeding and the administration of a few simple drugs, the relief of the patients stopped. Hospitals, as a rule, had no regular medical service until the sixteenth century. The mission of the medieval hospitals was to provide nursing, food, rest, and religious consolation. From the writings of the time the fact will be gathered that the best the age afforded was given to the sick. Miss Spearman points out that in judging of the adequacy of the care of patients in medieval hospitals, it must be borne in mind that the standard of comfort in all departments has risen immensely. The supply of food was to be unlimited as far as health permitted and the quality of the best. The following were the statutes as to the beds: The beds were to be of the best length and breadth for repose, and each should have its coverture and its sheets clean. In some hospitals little beds were provided for children born in the house, and not the least interesting feature of the medieval hospital was that in many of them children thus born were, in the case of their mother's death, kept in the house up to an age varying from seven to ten years. At the great hospital of St. Bartholomew, London, the former was the age prescribed. Referring to the architecture of these buildings the writer says: "Built for the most part when Romanesque was passing into Gothic, or when Gothic was at its best, the hospitals, as can be seen from those still in existence and from remains, were marked by great beauty and even by luxury of architecture."

Eadmar, monk of Canterbury, writing of the buildings of the hospital of St. Gregory in that city speaks of it as "*lapideam domum decentem et amplam construxit*," "A stone house seemly and commodious." The great dormitories and other rooms used by the patients and the religious were built with vaulted roofs and presented an ecclesiastical appearance, indeed the entire scheme of the buildings and management was evolved from the brains of priests and churchmen, and the medieval hospital was intended to serve the purpose of caring for a human being's spiritual as well as physical needs. The nursing seems to have been good and night nurses were supplied. The number of general hospitals in proportion to the population was very large, of the something like 16,000 hospitals existing in France 480 date from before the sixteenth century.

A very large number of institutions for treating the sick in the Middle Ages were what were known as lazar houses. Leprosy was then very prevalent in Europe and in Great Britain, and as its tuberculous form was deemed to be highly contagious, its victims were rigidly secluded.

"The status of the leprous," says Miss Spearman, "varied from hospital to hospital according to their endowment. In some they received all that was needful for their support; in others, a portion of the revenue was assigned to each, and if this did not suffice, it could be eked out by private resources, which took principally the form of begging, either at the gate of their hospital or of the town."

Insane hospitals were by no means common in the Middle Ages. Insanity then was a much rarer disease than it is at present, and, though in the early Christian period treatment of the insane made great progress—so much so that in the opinion of Miss Spearman it is doubtful whether its theory is surpassed in our own time—there was a falling off in the "Dark Ages."

There is some record of a certain number of early asylums. Of this nature was that founded in Constantinople in 321 and that at Jerusalem in 495, and it was with Paulus Aquieta, in the seventh century, that diagnosis and treatment reached their highest development.

Although medieval hospitals could not be compared, so far as scientific treatment was concerned,

with those of modern times, yet with regard to the care and comfort of the inmates it is to be doubted whether the sick in the Middle Ages who resorted to these institutions were not treated, on the whole, more humanely than in many of the up-to-date hospitals. As to leprosy, the fact is worthy of notice that segregation—which was strictly practised in medieval Europe—had the effect of driving the disease from that continent.

Fighting Tubbrculosis in Chicago.

The war against disease is being carried on steadily and with unabated zeal. Consumption is, on the whole, the malady with which the forces of sanitation and medicine are waging the most persistent fight. The reasons why this is so, are many. Tuberculosis is preëminently a disease of civilization, and flourishes most freely in large industrial centers. It is the most widely prevalent of all human affections, and the mortality from pulmonary tuberculosis is the most consistently large. It not only is the cause of an immense number of deaths, but it incapacitates its victims for a very long period.

Tuberculosis, under certain conditions, is also communicable, and, lastly, it is preventable, and even when acquired, if taken in time, is curable. No wonder, then, that a disease with the foregoing characteristics, should be fought strenuously.

In Great Britain the war against consumption has been conducted for a long time, with a fair measure of success. In France most vigorous efforts have been initiated to grapple successfully with the white plague, while in Germany the matter is being dealt with in the thorough manner with which the Teuton attacks such problems. The crusade against the malady in the United States has been somewhat intermittent; or to write with greater accuracy, in some parts of the country consumption has been combated judiciously and strenuously, but in other parts a lamentable apathy in regard to its ravages has been displayed. New York has well upheld her position as the most important city of the New World in this respect, and consumption is being battled with wherever met by means most suitable to the existing conditions. Chicago, too, is awaking to the perils of the situation, and has instituted measures to cope with the scourge. The committee on the prevention of tuberculosis of the visiting Nurse Association of Chicago has recently issued its preliminary report, together with a number of circulars bearing on the subject. The report points out that in Chicago no active work was done until 1903, when the committee referred to was formed. "Conditions existing in Chicago," the report goes on to say, "call emphatically for a united effort. There is a very limited number of hospitals which accept consumptives at all. The Visiting Nurse Association, which, through its staff of nurses, comes into constant contact with the consumptive poor, and the Bureau of Charities, whose work also is among this class, realized that only an organization with specially trained assistants could cope with the problem, and they resolved, therefore, to inaugurate a movement in Chicago similar to that in other cities." The committee have used every endeavor to ensure the success of the organization. Public-spirited citizens were invited to serve on the general committee, and responded to the appeal in the most gratifying manner. Two members of the committee, Drs. Hamilton and Klebs, have, during the past summer, visited Paris, New York, Boston, and Saranac, in which places movements against tuberculosis have been inaugurated, and investigated the various methods of the societies for the prevention of tuberculosis, sanatoria, dispensaries, health boards, etc. A popular propaganda has been undertaken, and the clinical and hygienic work has been carried out on a systematic plan. Literature and statistics on tuberculosis have been kept on file at the central office, while Dr. Klebs has loaned his library on tuberculosis to the office. The circulars published contain directions to district physicians, directions to nurses, general suggestions to nurses, and general directions as to keeping records. Thus it will be observed that Chicago, although somewhat late to recognize the necessity of fighting consumption, is determined to make up for lost time, and, with true Western energy, is straining every nerve to render the outcome of the fight successful.

News of the Week.

Surgeon N. Senn, Japanese Army.—A press despatch from San Francisco, dated February 5, states that Dr. N. Senn has arrived at that port from Tahiti, and is hurrying back to Chicago to arrange his private affairs and prepare himself for an expected call to Japan to assume charge of the Red Cross work with the Japanese army. He said: "If my services are needed I will quickly respond, and will probably take a corps of surgeons with me. The Red Cross Society of Japan, of which I have the honor to be a member, is composed of 8,000 members, and is the strongest organization of its kind in the world. It is absolutely ready for war, and its ambulances and field corps could be called to a battlefield on the very shortest notice."

An Epidemic of Appendicitis.—Dr. Sheldon of Madison, Wis., is reported in the *New York Times* as a propounder of the theory that appendicitis is a contagious disease of microbic origin. This hypothesis, he believes, offers the only explanation of the epidemic of the disease which he says now prevails in the country. He would doubtless hold as confirmatory of this theory the story of three sisters in Augusta, Ga., who were all operated on for appendicitis in one day. The three girls were students at an academy in Washington, Ga. One was attacked on Saturday, another on Sunday, and the third on Monday, and the three operations were performed on Tuesday. They were all brought to Augusta for the operations. The father of the girls was himself operated on for appendicitis a few months ago.

Lectures on Tuberculosis at the Henry Phipps Institute.—The next lecture in the international course on Tuberculosis, under the auspices of the Henry Phipps Institute, Philadelphia, will be given by Dr. Hermann M. Biggs of New York on Monday evening, February 15, the subject being "The Administrative Control of Tuberculosis." The profession in general is cordially invited to attend this lecture.

Anniversary Celebration of the Philadelphia Neurological Society.—On the evening of January 27 a dinner was given at the University Club to celebrate the twentieth anniversary of the foundation of this society. Toasts were responded to as follows: "The Dawn of American Neurology," by Dr. S. Weir Mitchell; "Neurology in New York," by Dr. E. C. Spitzka; "American Neurology of To-day," by Dr. George Lincoln Walton of Boston; "The Relation of Medicine to Neurology," by Dr. Wharton Sinkler, and "Neurology in Philadelphia," by Dr. Charles K. Mills.

The Obersteiner-Redlich Theory of Tabes Dorsalis.—In the article with this title in the Medical Record of January 30, Dr. Hassin writes, there was a transposition of prepositions in the fifth and sixth lines of the second paragraph on page 168. The line

should read: "to the spinal roots some pathological process extends from the pia mater," etc.

Examinations for Army Medical Service.—The examination of applicants for appointment as Assistant Surgeon in the United States Army will be resumed in Washington immediately after the close of the present session of the Army Medical School; it will embrace the full examination (as heretofore), at the conclusion of which those found qualified will be commissioned. Full information as to the requisite qualifications for appearance for examination, method of application, nature, and scope of examination, etc., may be obtained upon application to the Surgeon-General, U. S. Army, Washington, D. C. The examining board will probably reassemble about the middle of April next, and those desiring to present themselves before the board should make application at once. Applicants are restricted in age to thirty years, and one year's hospital experience or its equivalent in private practice is required.

Civil-service Examinations for the State and County Service.—The State Civil-service Commission announces general examinations to be held February 27, 1904, to fill the following positions among others: Apothecary in State hospitals and institutions; physical instructor in State institutions; physicians in State hospitals and institutions of both regular and homeœopathic schools; pupil nurse, Erie County Hospital. Applications for these examinations must be made on or before February 22. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

Dr. Lindsley and the Mobile Quarantine Board.—Dr. J. B. Lindsley was arrested on January 27, on his arrival at Mobile from Havana. He is charged with criminal libel of members of the Quarantine Board of Mobile Bay. He had a controversy last summer with the board regarding quarantine restrictions against ships from Havana, claiming that, Havana being a clean port, the restrictions were unnecessary, and published in a New Orleans paper a severe arraignment of the board. This was his first visit to Mobile since the publication. Dr. Lindsley surrendered at the sheriff's office, and, after making a bond for his appearance at the next term of the City Court, was released. Dr. Lindsley said that he could substantiate the charges made against the local Quarantine Board by their own books, if given an opportunity.

The Milk Supply of Philadelphia was the subject of discussion before the Keystone Veterinary Medical Association held in Philadelphia on January 19. The discussion was opened with a paper entitled "The Milk Supply of Hospitals and Public Institutions," by Dr. Leonard Pearson, State Veterinarian. He pointed out that when the producer sold his milk directly to the consumer, each took an interest in the quality of the milk, and it was maintained at a high standard. With the growth of the business, and the advent of the middleman, the object on either side seemed to be to drive the best bargain, the quality of the milk becoming in a measure a subordinate matter. As a result, while the largest portion of the milk supplied to Philadelphia was good and wholesome, not a little was bad, even to the point of causing disease. Mr. Henry W. Jeffers, B.S., then read a paper entitled "The Production of Certified Milk." He described an ideal dairy, and the methods for securing healthy cows and keeping them in clean and healthy condition, the care of the surroundings, of the attendants, and the utensils, and the protection of the milk against contamination and deterioration. He pointed out the necessarily increased cost of certified milk, and the unwillingness of a large part of the community to pay more than the established price for the better product. Even the hospitals, as a rule, took no steps to protect themselves, the prime consideration being apparently to buy the cheapest milk. Through the initiative of Dr. Martin, Director of Public Health and Charities, arrangements had been entered into by means of which the milk supply for the Philadelphia Hospital was to be regularly tested and required to conform with certain reasonable standards. Mr. George Abbott next presented a communication entitled "The Dealer's Position with Reference to Certified Milk." He dwelt upon the slight encouragement given to the dealer in the preparation of certified milk, only a comparatively small amount being bought by the community, so that, as a rule, the dealer was unable to conduct this department of his business at a profit. Nevertheless, he expressed the belief that certified milk had come to stay. Dr. Samuel McC. Hamill read a paper entitled "The Milk Commission of the Philadelphia Pediatric Society," detailing the work of this body and its method of procedure. A number of dairies had expressed a willingness to adopt the standards of the Commission and, having complied with them, were dispensing certified milk. Dr. M. P. Ravenel, the bacteriologist of the Milk Commission, presented a communication entitled "The Work of the Bateriologist in the Improvement of the City Milk Supply." He described the sources of milk contamination, and the causes of deterioration, as well as the methods of examination for bacteria, and he showed how such systematic scrutiny served as a check upon the dairyman. The work was supplemented by bacteriological examinations of discharges from the throats and noses of those employed about the dairy who presented signs of illness, and likewise of diseased parts of cows supplying milk. Dr. Chas. A. Fife presented a communication entitled "The Work of the Chemist in the Improvement of the City Milk Supply." Dr. C. J. Marshall read a paper on "The Work of the Veterinarian in the Improvement of the City Milk-supply." He urged the necessity of instructing producers of milk in sanitary methods. Dr. A. C. Abbott, president of the Bureau of Health, spoke of "Market Milk from the Standpoint of the Consumer." He related instances of milk-contamination at the dairy and the spread of disease in the city through the sale of such milk.

Increased Appropriation Needed for the Cincinnati Hospital.—The Board of Medical Directors of the Cincinnati Hospital have asked for $50,000 additional appropriation to meet the increased expenses of the institution, which were higher this past year than ever before.

Quarantine Raised at Wells College.—The women students of Wells College at Aurora were allowed their liberty on February 6, for the first time in two weeks, having been under strict quarantine during this period to prevent the spread of smallpox. The young lady who had varioloid has entirely recovered and no new cases developed during the period of quarantine.

The Second Latin-American Congress of Medicine and Hygiene will be held in Buenos Ayres on April 3–10, 1904. In connection with the congress there will be an exposition of hygiene which will remain open through the month of May. The subjects announced for set discussion, in addition to a large number of individual papers on the program, are as follows: 1. Causes of Deaf-mutism in the Argentine Republic; 2. Prevention of Blindness; 3. Etiology of Goiter; 4. *X*-rays in Surgery; 5. Distocia in the

Argentine Republic; 6. Hematology in Surgery; 7. Strictures of the Urethra; 8. Surgical Interference in Exophthalmic Goiter; 9. Treatment of Cancer; 10. Treatment of Laryngeal Tuberculosis; 11. Treatment of Tuberculosis of the Eye; and 12. Biliary Lithiasis and Its Complications.

Antivivisectionists on a Hunt for Evidence.—The Humane Society of Cincinnati is trying to collect evidence enough for the arrest of some of the workers in the Cincinnati Hospital Laboratory. These physicians are trying a series of experiments on animals to determine the stages of development of hydrophobia.

The Medical Society of the Missouri Valley.—The next meeting of this society will be held at Lincoln, Neb., on March 24 and 25, 1904, under the presidency of Dr. A. D. Wilkinson of Lincoln. A symposium on pneumonia will be a feature of the program. Those desirous of presenting papers should send the titles to the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo., not later than February 20. At this meeting the draft of a new constitution and by-laws will be submitted, and a proposition will be debated to make this society an auxiliary of the American Medical Association.

Alexian Brothers' Hospital, Chicago.—During 1903 this hospital cared for 3,062 patients; 1,932 were discharged cured; 488 discharged improved, and 91 discharged unimproved. The deaths of the year numbered 333. Of these, 126 were in a dying condition when admitted to the hospital.

Expectoration on the Sidewalks.—The members of the Chicago Progressive Health Club are urging the wide publicity of the anti-expectoration ordinance, aided by the press and printed cards. An anti-expectoration ordinance was passed by the City Council three years ago, but has never been enforced. Recently, however, Alderman Goldzier drafted a memorial for presentation to the City Council to the effect that the police and health departments shall be instructed to cause the arrest of persons who flagrantly and offensively violate the ordinance by spitting on sidewalks, etc.

Medical Licensure in Missouri.—The State Board of Health of Missouri, in December, examined forty-seven applicants to practise medicine. Of this number, twelve failed to make the required average (75 per cent.). During the year 1903 there were 138 applicants for certificates; 31 midwives were examined for certificates; 254 physicians were licensed to practise on diplomas, and 29 duplicate certificates were issued.

Polish Medical Congress.—The tenth quadrennial Congress of Polish Physicians and Scientists will be held at Lemberg, Austrian Poland, on July 20–24, 1904. Prof. E. Machek is chairman, and Prof. W. Sieradzki is secretary of the committee of arrangements. The representative of the committee for the United States is Dr. Francis E. Fronczak, 508 Fillmore Avenue, Buffalo, N. Y.

Columbus Epidemic Increasing.—The typhoid-fever epidemic in Columbus, Ohio, is spreading with alarming rapidity, the total has now reached 1,000 cases. On January 30 eighty-one new cases were reported. Deaths have been comparatively few, as the disease is in rather a light form.

Dr. Arthur B. Ancker has withdrawn his acceptance of the position of Superintendent of the Presbyterian Hospital, Chicago, and his resignation as Superintendent of the City Hospital, St. Paul, Minn.

Amusement Hall for the Insane.—A new amusement hall is projected for the inmates of the Longview Insane Asylum of Hamilton County, Ohio, as soon as the bond issue now in the hands of the Legislature is assured. At present the attic of one of the buildings is used for this purpose.

Christ's Hospital, Cincinnati, after being closed for seven months for improvements, will be open for public inspection this week. The formal opening will be held next month.

Ordinance Providing for Muzzling of Chicago Dogs.—At a meeting of the Chicago City Council, held January 18, an ordinance was passed providing that dogs must be muzzled all the year round unless led by a chain. The fine imposed for the violation of this ordinance is to be not less than $2 or more than $10.

Philadelphia Pediatric Society.—At a stated meeting, held January 12, Dr. D. L. Edsall related a case of endocarditis with valvular lesions and great enlargement of the heart, associated with physical signs of pneumonia involving the lung behind the heart, and the latter of which he was inclined to attribute to pressure upon the lung by the enlarged heart. That this explanation was correct seemed to be proved by the fact that the physical signs referable to the lungs disappeared when the patient was made to lie for a time on the right side of the body, and permanently with the recovery of the child. Dr. Edsall had observed a similar association in cases of pericarditis with effusion, although he had not previously been able to demonstrate the accuracy of the explanation to his satisfaction. Dr. S. McC. Hamill exhibited a girl of eleven years with signs suggesting aneurysm of the aortic arch. The child was undersized, with a high palatal arch, roughness of the skin, an undue development of hair on the body, evidently a mouth-breather, in some degree deficient mentally. She had never presented cyanosis, and there was no family history and no symptoms suggestive of syphilis. The urine was free from albumin and sugar, but there were spots of hemorrhage in the fundus of one eye. The area of cardiac dulness was much increased, and various systolic and diastolic murmurs were present over the heart. A systolic murmur was audible also to the left of the vertebral column at the level of the transverse process of the first cervical vertebra. The left pulse was smaller than the right, but instrumental measurement indicated higher arterial tension in the left than in the right upper extremity. Dr. Hamill exhibited also a child about four years old, with a tumor in the right flank, which developed shortly after a fall with injury to the region affected. The twenty-five cases observed at the Philadelphia Hospital. The condition of the blood with respect mass was irregularly nodular in shape, and presented from time to time variations in shape, without change in the quantity of urine discharged. The urine had been examined once, but no abnormality was found. There had been no jaundice. The condition was believed to be a cystic kidney, which had been displaced as a result of the fall, the flow of urine being obstructed from time to time, the subsidence of the enlargement coinciding with a release of the obstruction and the escape of the pent-up fluid. Dr. Hamill also reported a case of meningitis with exaggerated reflexes, in which a tap on the patellar tendon excited not only the knee-jerk, but also extension of the foot on the leg. The latter phenomenon was elicited also by tapping the knee to one side of the patellar tendon. Dr. J. H. McKee exhibited a case of enormous hydrocephalus in a child ten and a half months old, in whom the condition had been observed since the age of three months. Convulsions occurred repeatedly. There was nothing in the history suggestive of an etiological

factor. Lumbar puncture had been practised and a small amount of fluid removed, without affording any relief. The condition becoming desperate, the lateral ventricle of the brain was punctured through the anterior fontanelle, and a considerable amount of fluid evacuated. The convulsions ceased and the head diminished somewhat in size, the improvement having persisted for a period of more than six weeks. Dr. A. P. Francine read a paper entitled "Diastasis of the Recti Muscles in Rickets." He pointed out that this association is not generally recognized or commonly referred to in the textbooks. He had observed it in seven of ten cases in which he had looked for it. The phenomenon is difficult to elicit in young children, who cannot operate in the examination by efforts to elevate the head and shoulders while in the recumbent position. Separation of the upper half of the abdominal recti muscles is not rare in healthy children, but in rachitic children the separation involves the muscles throughout their entire extent. Dr. D. J. Milton Miller read the "Annual Address of the Retiring President," reviewing the work of the society for the year, and commending its members to continued effort in the development of the special department of medicine in which they are particularly interested.

Philadelphia County Medical Society.—At a stated meeting, held January 13, Dr. A. Helena Goodwin read a paper entitled "Bad Nauheim and the Schott Treatment." She described in an interesting manner the waters of Nauheim, the manner and the method of employing the baths and the selection of the cases for treatment, as well as the measures to be pursued in the after-treatment. The good effects of the baths are attributed to the temperature of the waters and to the contained carbonic dioxid and salts. Not a little credit is due also to the accompanying exercises. In sending patients to the resort physicians should be careful to see that they consult some trustworthy local physician, who will either carry out the treatment prescribed or will institute suitable treatment in his own discretion. Dr. John M. Swan read a paper entitled "The Blood in Patients Suffering from Pulmonary Tuberculosis," based upon studies in to the hæmoglobin-percentage and the number of erythrocytes and of leucocytes, as well as differential relations of the leucocytes, was not found distinctive in any of the three stages into which the disease was divided. There was, in general, a reduction in hæmoglobin and in erythrocytes, with at times an increase in leucocytes, affecting principally the polymorphonuclear leucocytes and occasionally also the eosinophiles. Dr. Barton Cooke Hirst read a paper entitled "The Plastic Surgery in the University Maternity for the Year 1903." He related that it is now the practice to repair lacerations of the perineum of the anterior and posterior walls of the vagina and of the cervix uteri as soon after parturition as possible, some times at once and always within the first week or thereabouts, thus sparing the patient the necessity of undergoing a subsequent operation and also the discomfort resulting from her disorder in the interval. The results have been eminently satisfactory, and Dr. Hirst has extended the practice to his private work as well. Dr. Wm. L. Rodman presented a communication entitled "The Operative Treatment of Malignant Disease (Mammary Glands, Rectum, Penis, and Lips)." He pointed out the absence of a capsule of the mammary gland and he dwelt upon the lymphatic circulation. He expressed the opinion that permanent recovery should follow in one-third of the cases of carcinoma of the breast operated on. The operation should always be a radical one, with removal of the pectoral muscles and of the contents of the axilla. Operations on the rectum are not promising, while those on the penis have yielded good results in Dr. Rodman's hands. Malignant disease of the lips is most amenable to surgical treatment. Dr. Alfred Stengel presented the report of the committee appointed to consider the question of the prevention of the communication of contagious diseases, particularly in private practice, and with special reference to scarlet fever. The committee recommended, among other things, cumpulsory vaccination and revaccination, notification of tuberculosis, the requirement that householders, in addition to physicians, shall notify the Bureau of Health of the existence of notifiable diseases.

The Late Dr. Frank W. Shaw.—At a special meeting of the Medical Board of the Norwegian Hospital, held January 11, 1904, the following resolutions were unanimously adopted respecting the death of the late member of the Board, Dr. Frank W. Shaw: "That we, the members of the staff, fully realize and feel that by his death the entire medical profession has sustained a grievous and lasting loss; that we tender our sincerest sympathy to his family in their bereavement; that a copy of these resolutions be sent to the family and to the medical journals of our city; and that these resolutions be spread in full upon the minutes of this board."

Obituary Notes.—Dr. Joseph G. Rooney of West Hoboken, N. J., died at St. Mary's Hospital on February 4, at the age of thirty-seven years. He was a graduate of the Medical Department of the New York University in the class of 1891. Dr. Rooney's death adds another name to the long list of martyrs to duty among medical men. During a fire in Hoboken on January 18 five firemen were injured and Dr. Rooney was called to minister to them. It was bitterly cold, but the physician, who was obliged to work with bare hands and rolled-up sleeves, refused to leave his patients until all their necessities had been attended to. In consequence of the exposure his hands were frostbitten and gangrene supervened, causing his death. A widow survives him.

Dr. John R. Hinkson died at his home in Blissville, Borough of Brooklyn, on February 5, of pneumonia. He was forty-eight years of age and a graduate of the Bellevue Hospital Medical College in the class of 1889. He had a large practice and was greatly beloved by the poor for his large-hearted generosity and devotion to all who needed his services.

Dr. Joseph B. Roe died at Woodbury, N. J., on February 5, at the age of sixty-eight years. He was graduated from Princeton University in the class of 1858, and from the Medical Department of the University of Pennsylvania in the class of 1861. He served for four years in the Medical Department of the United States army during the Civil War. He was at one time a member of the New Jersey Assembly, and from 1887 to 1890 a member of the State Senate. He also served two terms as postmaster at Woodbury.

Dr. H. B. Buehler died at Harrisburg, Pa., on February 1, at the age of sixty-five years. He was a surgeon in the United States Army during the Civil War.

Dr. W. S. Charlton died in Philadelphia on February 2, at the age of forty-six years. He was graduated from the Medical Department of the University of Pennsylvania, in the class of 1883.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL SOCIETY—CANCER—HYPERTROPHIC PULMONARY OSTEOARTHROPATHY—OXFORD PROFESSORSHIPS—EDINBURGH STUDENTS' DOINGS—THE BALLACHULISH VICTORY—TEACHING OF HYGIENE AND TEMPERANCE—THE LATE DR. THIN.

LONDON, January 22, 1904.

At the Royal Society last evening an important research on cancer was communicated by Drs. Bashford and Murray which seems to confirm and extend the results presented to the society a month ago by Drs. Farmer, Moore, and Walker. These two groups of investigators have been working quite independently of each other, so that the coincidence of their results is of the greater value. The remarkable resemblance of the so-called cancer cells to those from which sexual cells are ultimately derived was emphasized by the first group of investigators by applying the word "gametoid" to active cancer cells, thus indicating their belief that although they do not become normal reproductive cells, they are of the same nature, and that nutritional or other derangement may account for the differences. The "cancer cells" originate from the cells at the advancing edge of the growth by a process of nuclear division identical with that through which sexual cells pass. A study of the changes that occur in certain abnormal vegetable structures originally led the authors to consider the significance of the obscure nuclear divisions of the cells in malignant tumors. The parasitic habit of these growths so often referred to and their clinical manifestations lend support to the views advanced by the two papers before the society. The second confirms the first and adds to it, while it corroborates various other observations. Thus it shows that cancer is widely distributed through the vertebrate animals. Further, the remarkable resemblance to sexual cells referred to above can be observed in the other vertebrates as well as in man. Drs. Bashford and Murray have, moreover, transplanted cancer from one animal to another of the same species. The independence of the cells of the neoplasm of the tissues they are invading is shown by microscopical examination. It would seem that the cancer problem is thus a cell problem, and its solution must be sought there.

It may be objected that somatic cells can hardly take on the characters of generative tissues. But such an occurrence is common enough in the vegetable kingdom. We have, however, in our anatomical studies been so accustomed to regard the somatic and generative cells as quite distinct that a contrary view arrests attention if not doubt. Cohnheim's theory of cancer accorded very well with the prevailing notion, but will have to undergo great changes or be rejected in consequence of the new researches. These investigations certainly point out the direction for further research, and there are many ardent workers prepared to follow. But with great promise of fruitful discoveries it is too soon to talk, as some are already doing, of the reduction of cancer to the position of a curable disease

At the Royal Medico-chirurgical Society Dr. Symes Thompson read a paper on Hypertrophic Pulmonary Osteoarthropathy founded on four cases with two necropsies: in one of these secondary carcinoma of the lung, in the other spinal caries, was revealed post mortem. Some account was given of twenty necropsies previously recorded and also of the clinical details of seventy-seven cases. The absence of softening or suppuration favored the view that toxins only rather than bacteria were present and the symmetry pointed to the same conclusion. The cause suggested by the author was retention in the blood of volatile toxins which normally would be got rid of by the lungs, the elimination being prevented by any pulmonary disease interfering with normal respiratory interchange.

The essential toxic foci might or might not be in the lungs; those associated with psoas abscess or even with diarrhœa were the chief. One of the author's cases favored this view. It was sacculated bronchiectasis and the employing of the cavities coincided with a subsidence of the joint attacks.

Dr. T. Williams said that though he had seen numerous cases of bronchiectasis, he had very seldom known the osteoarthritis to follow. It was difficult to see how the variations of the joint affection with the conditions of the discharge were produced.

Dr. Percy Kidd related four cases he had seen. In one there was tuberculosis of the sternum with only slight lung lesion. In another there was marked thickening round the joint, but no change within, confirmed after death. He agreed that the disease was probably due to a toxin. In early stages it closely resembled rheumatoid arthritis.

Dr. Rob. Maguire thought the theory of the lung being a sort of gland should not be forgotten. Acute attacks of dyspnœa without signs of lung disease might be due to altered function of this gland. He mentioned a case in which intravenous injections of formaldehyde reduced the temperature and swelling of the joints as well as the sputum—a result just the reverse of that in Dr. Thompson's cases, for in them the joints improved as the sputum increased. He thought the joint affection due to invasion of a microorganism.

Mr. Spencer thought the toxic theory insufficient and suggested that a chronic venous congestion of the bone-ends might play a part. The early stages closely resembled chronic septic states. He mentioned the joint troubles of "mother-of-pearl" workers (who were mostly young girls), which might depend on the inhalation of dust.

Dr. Newton Pitt said thickening of the bones, clubbed fingers, and joint troubles were all present in advanced cases, but in the early stages only one of these, perhaps, which added to the difficulties of diagnosis. He suggested that marrow changes should be sought for.

Dr. Russell Wells remarked that in the laboratory organisms grew best in certain media, so when they attacked the human body they might affect particular tissues. As the disease attacked cartilage and fibrous tissues in the lung, so it affected the joints in which these tissues were found.

Sir J. Bundon Sanderson has resigned the Regius Professorship of Medicine at the University of Oxford, and quite a dispute has arisen about the future of the chair. Shall it become a chair of Pathology, or shall it remain a clinical professorship? There is something to be said on each side, hence much difference of opinion. It is not easy for Oxford to become a clinical school and her graduates come to London for hospital work after passing in the scientific part of the curriculum. It seems there is a financial straitness which has led to the proposed change, otherwise pathology might be sufficiently endowed and the clinical professorship also maintained. Here is a chance for a millionaire.

I am informed that the students of the University of Edinburgh yesterday afternoon indulged in their usual boisterous and noisy demonstrations on the occasion of the Lord Rector's address. The Attorney-General, Sir Rob. Finlay, is their chosen Lord Rector, and Mr. Balfour presided in his capacity of Chancellor of the University. But the presence of the Premier had no restraining influence, and even when he called on the Dean of the Faculty of Divinity to open the proceedings with prayer, a decent hearing was not given. Sir R. Finlay raced through an address of which nothing could be heard, but it was reported to be on international arbitration. Really it is about time university students conducted themselves more like sensible young men.

The Ballachulish quarrymen have utterly defeated the directors who assumed to appoint the quarry doctor. You will remember I told you at the outset of this extraordinary dispute that the men determined to exercise their inherent right to choose the doctor. He was paid by their contributions, collected or deducted by the officials as a matter of convenience, but the company did not give a penny toward the fund. How the board could be so stupid as to defy the men in such an unjust quarrel is only accountable on the old explanation of a board's deficiency of body and soul. The quarrymen have stood to their guns on behalf of their doctor, who is now reinstated as their tried and trusted adviser. Happy doctor to have such confidence!

To-day the circulation is begun of a petition to the central Boards of Education, the object of which is to secure instruction in all primary schools in the rudiments of health and temperance. The promoters of the petition are hoping to have the general support of the medical profession, to obtain which a copy will be sent during the next few days to every practitioner.

Dr. George Thin, one of our leading dermatologists, died at Nice on the 27th ult. of heart disease. He had given up work for a year or more and had gone south for the winter. He was for some time in China, where he attained considerable experience in tropical diseases. His work on "Psilosis or Sprue" must be well known to you. He was a valuable adviser in difficult cases and will be greatly missed.

Popular Addresses on Tuberculosis.—Dr. B. F. Lyle, Superintendent of the Cincinnati Branch Hospital for Consumptives, delivered a popular lecture on "The Home Treatment of Consumption and Contagious Diseases." This is the second of a series of popular lectures given by representative men.

THE PSYCHICAL RELATION OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir: When one reads the letter of Dr. J. A. De Santos Saxe on the above subject, which appeared in your esteemed paper of January 23, the impression is conveyed that my article on "Phthisiophobia and a Plea for Justice to the Consumptive" (Medical Record, January 2, 1904) had no foundation, and that from Dr. Saxe's former contribution no possible deduction as to his furthering phthisiophobia could be made.

If, as Dr. Saxe modestly claims, his article "The Psychical Relation of Tuberculosis in Fact and Fiction" (*New York Medical Journal*, August 1 and 8, 1903) does not pretend to advance new or original views on the mental characteristics of the tuberculous patient, why, then, do we read under his sub-chapter, "The Relation of Tuberculosis to Crime," the following: "To me this account shows the germination of a homicidal tendency, which is the resultant of the psychical defects that I have outlined in my analysis of the average consumptive's mental peculiarities. Here, psychasthenia, the loss of self-control, and the rise of brute selfishness have com bined to distort the clearness of ethical perception."

It is true that Dr. Saxe does not draw this conclusion from his own cases, but from *one* case from Dr. Fanoni's practice. Now, in the "Standard Dictionary," the word "average," when applied to persons in this sense, is defined as *possessing general or typical characteristics*. Thus, according to Dr. Saxe's conclusions, the general and typical characteristics of a consumptive are psychasthenia, the loss of self-control, and the rise of brute selfishness, resulting in a distortion of the clearness of ethical perception.
